SULFAMERAZINE CLINICAL EVALUATION IN 400 CASES*

HARRISON F. FLIPPIN, M.D., F.A.C.P.,† JOHN G. REINHOLD, Ph.D.‡
and
WILLIAM I. GEFTER, M.D.§

It is generally recognized that sulfadiazine, by virtue of its equal or superior antibacterial efficacy and its relatively low toxicity, is the most satisfactory of the sulfonamide compounds now in common use. Despite these attributes, sulfadiazine is not an ideal chemotherapeutic agent since certain shortcomings are apparent: (1) the drug is slowly absorbed from the gastrointestinal tract¹ and (2) at times it gives rise to serious toxic reactions, particularly in the urinary tract.² Attempts to find a drug possessing definite superiority for clinical use over sulfadiazine have directed attention to the methyl derivatives of

* From the Philadelphia General Hospital Committee for the Study of Pneumonia which also includes J. H. Clark, M.D. and S. Brandt Rose, M.D. The authors are indebted to Mrs. Rose Polowsky Feldman for technical assistance.

sulfadiazine Of these, sulfamerazine has warranted clinical trial because of its therapeutic effectiveness against experimental infections, its pharmacologic behavior, and its relatively low toxicity in animals This report includes a brief review of the chemical and pharmacological data pertaining to sulfamerazine and presents the results of our clinical experience with its use in the treatment of a variety of acute infections

Sulfamerazine

Sulfamerazine (2-sulfanilamido-4-methyl-pyrimidine, sulfamethyldiazine), synthesized by two groups of investigators,^{3, 4} is one of the methyl homologues of sulfadiazine The structural formulas of sulfadiazine and sulfamerazine are shown in Figure 142

Fig 142 -Structural formulas of sulfadiazine and sulfamerazine.

ANIMAL EXPERIMENTS

The therapeutic activity of sulfamerazine was described by Roblin, Williams, Winnek and English³ at the same time that they reported on that of sulfadiazine It was found that both of these drugs were considerably more active against streptococcal pneumococcal and staphylococcal infections in mice than sulfanilamide, sulfapyridine, or sulfathiazole Pharmacologic studies by Welch, Mattis, Latven, Benson and Shiels⁵ in various species of laboratory animals have indicated that sulfamerazine is more rapidly and more completely absorbed from the gastrointestinal tract and more slowly excreted by the kidney than is sulfadiazine Toxicologic observations by this same group of

workers suggested that sulfamerazine is no more toxic in experimental animals than is sulfadiazine, when a comparison is made on the basis of blood concentration of the drugs. In these toxicity experiments, particular attention was given to the possibility of neuropathologic changes, because of past clinical experience with the sulfonamides containing a methyl group (sulfamethylthiazole, sulfanilyl dimethylsulfanilamide).⁶ It was

FREE DRUG LEVEL

mgm./100 cc

Fig. 143. Average levels of free drug after single oral 3-gm dose of sulfanilamide, sulfadiazine, and sulfamerazine.

found that dogs or monkeys, given large doses of sulfamerazine over thirty-day periods showed no evidence of nerve injury, but chickens with high blood concentration of the drug developed definite nerve lesions, although the changes were no greater than those resulting from lower blood levels of sulfadiazine in the same species.

ABSORPTION, DISTRIBUTION AND EXCRETION STUDIES

Oral administration of a single dose of 3 gm of sulfamerazine is followed by a rapid rise in its concentration in plasma to higher levels that are sustained for a longer period of time^{8 5 7} than after ingestion of the same amount of sulfadiazine¹ (Fig 143) Patients receiving 1 gm every four hours after the initial 3-gm dose maintained an average plasma concentration of sul-

Fig 144—Average daily plasma levels of free drug in patients receiving sulfamerazine therapy

famerazine (free) of 15.4 mg per 100 cc, those who received 1 gm every six hours, 12.7 mg per 100 cc, and those who received 1 gm every eight hours, 10.9 mg per 100 cc (Fig 144) Acetylation occurred to the same extent as with sulfadiazine, an average of about 15 per cent of the total concentration of sulfamerazine in plasma being present in acetylated form⁹ Sulfamerazine resembles sulfathiazole in that the erythrocytes contain much lower concentrations than the plasma.^{8 7} For this

reason determinations on serum or plasma are more informative than those made on whole blood

In cerebrospinal, pleural and ascitic fluids concentrations of sulfamerazine appear to be comparable to those of sulfadiazine, however, more data are needed. In a group of patients suffering from meningitis and being treated with sulfamerazine, the ratio of the sulfamerazine concentration in cerebrospinal fluid to that in plasma averaged 0.42 and ranged from 0.23 to 0.66 so that wide variations occurred⁹ in cerebrospinal fluid concentration. An apparent correlation between concentration of sulfamerazine in cerebrospinal fluid and response of meningococcal meningitis was not substantiated by application of statistical analysis.⁹

The higher concentrations of sulfamerazine in blood, compared with other sulfonamides, is in part due to more complete absorption from the gastro-intestinal tract and in part due to the slower rate of excretion.¹⁰ Sulfamerazine and its acetyl derivative are more soluble in urine than are the corresponding forms of sulfadiazine. Increasing the urine pH from 6 to 7 nearly doubles the solubility of both free sulfamerazine and acetyl sulfamerazine.¹¹ Because of the greater solubility and smaller amounts required to produce a given blood level and therapeutic response, the likelihood of crystal and concretum formation in the urinary tract is distinctly less than with sulfadiazine. However, the smaller intake of drug is offset to some extent by the more complete absorption of sulfamerazine.

CLINICAL MATERIAL AND METHODS

The response to treatment of the first 400 patients who received sulfamerazine* for at least twelve hours has been evaluated. The patients were studied at the Philadelphia General Hospital and the Hospitals of the University of Pennsylvania. The results have been included in part in recent reports from these institutions.^{7, 10, 11, 12} In general, the drug was given orally with an initial dose of 3 gm. followed by 1 gm. every four, six, or eight hours depending on the nature of the infection until the temperature had remained normal for forty-eight to seventy-two hours. In severe infections such as meningitis, encephalitis, or peritonitis the initial dose of 3 gm. was followed by

*Sharp and Doherty Laboratories, Glenside, Pa. The following preparations of sulfamerazine are used in this study:

administered by vein (5 per cent solution of sulfamerazine sodium in distilled water) and followed by 1 gm. by mouth every four hours. All pneumonia cases received the same initial dose by mouth, followed by 1 gm every eight hours, excepting the first twenty-three patients who received 1 gm every six hours. Patients with urinary tract infections received 2 gm of the drug daily at twelve-hour intervals in equal, divided doses. Infants and children received similar treatment with proportionately smaller dosages. With the exception of ten patients with gonococcal urethritis, all of the patients were hospitalized and were closely followed with appropriate laboratory studies. Fluids were given liberally, usually from 2000 to 3000 cc a day, but none of the patients received alkalis.

RESULTS OF SULFAMERAZINE THERAPY

Pneumococcal Infections

Pneumonia—During the course of this study, 199 adult patients with pneumococcal pneumonia were treated with sulfamerazine, of these, thirteen died (6.5 per cent mortality). In this group, thirty-four (17 per cent) had positive blood cultures and ten of these bacteremic patients died (29 per cent). Complications in this series of cases were relatively few. Two patients developed empyema, both recovering following thoracotomy. Endocarditis occurred in two patients, both of whom died. Two patients developed pneumococcal meningitis and these have been included in the meningitis group. The average total dosage for the successfully treated patients was 22.9 gm, given over a period averaging 6.4 days. Eight patients received specific serum and two received penicillin in addition to sulfamerazine.

As in former studies of the therapeutic effectiveness of sulfonamides in the treatment of pneumonia at the Philadelphia General Hospital, the medical services were so divided that the number of pneumonia patients receiving sulfamerazine was equal to that of a control group treated with sulfadiazine at the same time. The results¹² showed that the effects of the two drugs on final mortality were approximately the same, 7.5 per cent in the group of eighty adult patients treated with sulfamerazine as compared with 10 per cent in the group which received sulfadiazine. Sulfamerazine tended to lower the tem

perature somewhat more rapidly than did sulfadiazine, however the duration of chemotherapy and the incidence of complications were essentially the same for the two groups

TABLE 1

SUMMARY OF RESULTS OF SULFAMERAZINE IN 400 CASES

Causative Agent	Disease	Number of Patients	Died	Per Cent Died
Pneumococcus	Pneumonia	199 (34)	13 (10)	6.5 (29.4)
	Meningitis	12 (7)	10 (5)	83.3 (71.4)

()—Inactive host culture

Pneumococcal Meningitis—Sulfamerazine was used in the treatment of twelve adult patients with pneumococcal meningitis.

gitis with ten deaths (83 per cent mortality) In the fatal cases, four patients were moribund on admission to the hospital and died within twenty-four hours Two cases complicated pneumonia, one patient developed endocarditis, and another, a seventy-five-year-old male, died on the second day of treatment The remaining two patients responded initially to the drug but failed to recover Five of these patients received specific serum along with sulfamerazine and a single patient was given penicillin in addition In the two successfully treated cases only the drug was given, although in one a radical mastoidectomy was definitely instrumental in the patient's recovery¹³ The mortality of 83 per cent obtained in this small series of cases does not compare well with the results recently reported by Hodes, Smith and Ickes¹⁴ in which sixty cases of the disease were treated with sulfonamides with thirty-five deaths (58 per cent mortality), although other investigators^{15, 16, 17} in this field are of the belief that the present mortality of pneumococcal meningitis in unselected cases is in the vicinity of 80 per cent after all available methods of treatment are employed

Peritonitis—Two cases of pneumococcal peritonitis were successfully treated with sulfamerazine In both instances the diagnosis was made following laparotomy for suspected rupture of an abdominal viscus with resultant peritonitis

Meningococcal Infections

Meningitis—Within the period of this study, meningococcal meningitis was epidemic in Philadelphia and provided ample opportunity to test the efficacy of sulfamerazine Ninety-nine cases of the disease were treated with this drug with five deaths (5 per cent mortality) In this group there were fifteen patients in whom the diagnosis of meningococcal meningitis was based on a typical clinical picture, increased spinal fluid pressure, and a turbid cerebrospinal fluid with a high polymorphonuclear cell count, but without conclusive bacteriological evidence We believe these represent true cases of the disease and have therefore included them If the patients in this subgroup are excluded, however, the corrected mortality becomes 6 per cent Positive blood cultures were obtained in 13 per cent of the cases with one death (8 per cent mortality) In the fatal cases, two patients were moribund on admission to the hospital and died within

twenty-four hours, one had a right-sided torticollis of cerebral origin at the time treatment was started, and, although he received 105 gm of sulfamerazine, he finally died. Postmortem studies revealed areas of recent softening in the globus pallidus but no gross evidence of meningitis. The remaining two deaths occurred in patients in whom treatment was started late in the disease. For the successfully treated group, definite clinical improvement, manifested mainly by mental clarity, was apparent within forty-eight hours of drug therapy in approximately 70 per cent of the cases, although fever usually persisted for several days following the initial response. The average time observed before the recovered group became afebrile was five to six days.

Six of the patients received antimeningococcic serum in addition to sulfamerazine. Of these, one died. It is our feeling from observation of the clinical response in these cases that the same results would have probably been obtained without the use of the serum. One patient responded poorly to sulfamerazine, but made a brilliant recovery after the use of penicillin. Complications of the disease were observed in 15 per cent of the patients. These consisted of arthritis (six cases), ocular palsies (seven cases), Bell palsy (one case), and deafness (one case). Although eight of these complications were present on admission, all were transient, and recovery was complete. These results compare favorably with those recently reported from the Philadelphia General Hospital in which sulfadiazine was employed (12.5 per cent mortality).¹⁸

A single case of meningococcemia (without associated meningitis) was treated successfully with sulfamerazine.

Streptococcal and Staphylococcal Infections

Fifteen cases of hemolytic streptococcal infections of various types were treated with satisfactory recovery in all except for one patient with an acute hemolytic streptococcal endocarditis.

Four patients with subacute bacterial endocarditis with *Streptococcus viridans* bacteremia were treated unsuccessfully.

One patient with acute *Staphylococcus aureus* endocarditis failed to recover. A satisfactory therapeutic result was obtained in a single case of furunculosis of the external auditory canal due to *Staphylococcus aureus*.

gitis with ten deaths (83 per cent mortality) In the fatal cases, four patients were moribund on admission to the hospital and died within twenty-four hours Two cases complicated pneumonia, one patient developed endocarditis, and another, a seventy-five-year-old male, died on the second day of treatment The remaining two patients responded initially to the drug but failed to recover Five of these patients received specific serum along with sulfamerazine and a single patient was given penicillin in addition In the two successfully treated cases only the drug was given, although in one a radical mastoidectomy was definitely instrumental in the patient's recovery¹³ The mortality of 83 per cent obtained in this small series of cases does not compare well with the results recently reported by Hodes, Smith and Ickes¹⁴ in which sixty cases of the disease were treated with sulfonamides with thirty-five deaths (58 per cent mortality), although other investigators^{15, 16, 17} in this field are of the belief that the present mortality of pneumococcal meningitis in unselected cases is in the vicinity of 80 per cent after all available methods of treatment are employed

Meningococcal Infections

Meningitis—Within the period of this study, meningococcal meningitis was epidemic in Philadelphia and provided ample opportunity to test the efficacy of sulfamerazine Ninety-nine cases of the disease were treated with this drug with five deaths (5 per cent mortality) In this group there were fifteen patients in whom the diagnosis of meningococcal meningitis was based on a typical clinical picture, increased spinal fluid pressure, and a turbid cerebrospinal fluid with a high polymorphonuclear cell count, but without conclusive bacteriological evidence We believe these represent true cases of the disease and have therefore included them If the patients in this subgroup are excluded, however, the corrected mortality becomes 6 per cent Positive blood cultures were obtained in 13 per cent of the cases with one death (8 per cent mortality) In the fatal cases, two patients were moribund on admission to the hospital and died within

twenty-four hours, one had a right-sided torticollis of cerebral origin at the time treatment was started, and, although he received 105 gm of sulfamerazine, he finally died. Postmortem studies revealed areas of recent softening in the globus pallidus but no gross evidence of meningitis. The remaining two deaths occurred in patients in whom treatment was started late in the disease. For the successfully treated group, definite clinical improvement, manifested mainly by mental clarity, was apparent within forty-eight hours of drug therapy in approximately 70 per cent of the cases, although fever usually persisted for several days following the initial response. The average time observed before the recovered group became afebrile was five to six days.

Six of the patients received antimeningococcic serum in addition to sulfamerazine. Of these, one died. It is our feeling, from observation of the clinical response in these cases, that the same results would have probably been obtained without the use of the serum. One patient responded poorly to sulfamerazine, but made a brilliant recovery after the use of penicillin. Complications of the disease were observed in 15 per cent of the patients. These consisted of arthritis (six cases), ocular palsies (seven cases), Bell' palsy (one case), and deafness (one case). Although eight of these complications were present on admission, all were transient, and recovery was complete. These results compare favorably with those recently reported from the Philadelphia General Hospital in which sulfadiazine was employed (12.5 per cent mortality).¹⁸

A single case of meningococcemia (without associated meningitis) was treated successfully with sulfamerazine.

Streptococcal and Staphylococcal Infections

Fifteen cases of hemolytic streptococcal infections of various types were treated, with satisfactory recovery in all, except for one patient with an acute hemolytic streptococcal endocarditis.

Four patients with subacute bacterial endocarditis with *Streptococcus viridans* bacteremia were treated unsuccessfully.

One patient with acute *Staphylococcus aureus* endocarditis failed to recover. A satisfactory therapeutic result was obtained in a single case of furunculosis of the external auditory canals due to *Staphylococcus aureus*.

Influenzal Infections

There were five cases of influenzal meningitis due to the *Hemophilus influenzae* bacillus, with two deaths (40 per cent mortality). Two of the three recovered patients received appropriate serum therapy which may have contributed to the recovery.

Tuberculous Infections

Three patients with tuberculous pneumonia and six with tuberculous meningitis were treated with full doses of sulfamerazine, which showed no influence on the clinical progress in any of these cases. All died.

Gonococcal Infections

Satisfactory results were obtained in ten male patients with acute gonococcal urethritis. All recovered and no relapses followed.

Viral (?) Infections

There were twenty cases in this series which fulfilled the usual criteria for the clinical diagnosis of a probable viral infection. Sulfamerazine was employed in these patients for the following reasons: (1) the presence of an acute infection in which the diagnosis was not adequately substantiated by usual laboratory studies, (2) diagnostically, to determine the response of the disease to the drug, and (3) to prevent, if possible, secondary infection. Fifteen cases of *primary atypical pneumonia* were treated with sulfamerazine and, although the clinical response in this group was not so striking as that observed in the acute bacterial pneumonias, all patients recovered and no complications were seen. Three patients with benign lymphocytic choriomeningitis and two with acute encephalitis were given sulfamerazine with no deaths. In all five of these cases there was striking clinical improvement following the institution of chemotherapy, and it is possible that the drug did influence the course of the disease. Nevertheless, it is difficult to ascertain whether sulfamerazine had any beneficial effect in any of the above cases in which the clinical diagnosis of a viral infection has been made.

Unspecified Infections

There were eleven patients with bronchopneumonia to whom sulfamerazine was given. A variety of respiratory organisms, other than pneumococci, were isolated from the sputum samples of some of these patients. One died (9 per cent mortality). In eleven cases of acute pyelonephritis, cystitis, or trigonitis, sulfamerazine was used satisfactorily with no deaths. *Colon bacillus*, alone or with other organisms, was cultured from the urine of seven of these patients.

TOXIC MANIFESTATIONS OF SULFAMERAZINE

A summary of the various toxic manifestations encountered in 400 patients receiving sulfamerazine is given in Table 2.

TABLE 2

INCIDENCE OF TOXIC REACTIONS (400 CASES)

Toxic Reaction	Number of Cases	Per Cent
Gross hematuria	5	1.3
Acute loin pain	4	1.0
Dermatitis	12	3.0
Nausea and vomiting	5	1.3
Leukopenia	9	2.3
Thrombocytopenia	1	0.3
Fever	8	2.0
Psychosis	4	1.0

Forty-eight toxic reactions, attributable to the drug, were noted in thirty-eight patients (9.5 per cent).

Urinary Tract Complications

As mentioned above, one of the most significant difficulties associated with the use of sulfadiazine is its toxic effect upon the urinary tract, namely hematuria, urinary suppression, and renal colic. These complications are due in part, if not entirely, to the relative insolubility of sulfadiazine, especially its acetyl fraction. In view of the greater solubility of both sulfamerazine and acetylsulfamerazine in urine,⁵ as compared with sulfadiazine and acetylsulfadiazine, one might expect to encounter less urinary tract toxicity with the former. Special emphasis was placed on the possible toxic effect of sulfamerazine on the urinary system. A careful check was made as to fluid intake and output. Although alkalis were withheld, this was done for the purpose of giving the drug a more rigid test. Crystalluria, pre-

sumably due to the drug, was observed in approximately 15 per cent of the cases, but we have not considered this finding as being significant unless it was associated with other urinary complications. Likewise, the presence of occasional red blood cells in urine has not been classified as an urinary abnormality due to sulfamerazine because of the frequency with which microscopic hematuria is present with acute infections.

Gross hematuria occurred in five patients (13 per cent), four of whom experienced acute loin pain. In four of this subgroup (aged twenty, fifteen, fifty-five and eighteen years) acute loin pain and gross hematuria developed on the first, fifth, tenth and fourteenth¹⁰ days of treatment following 4, 16, 36 and 77 gm of the drug respectively. The urine in these cases contained many drug crystals as well as innumerable red blood cells. For each patient in this group the urinary output was 1200 cc., or better, for the twenty-four-hour periods preceding, the day of, and following the apparent ureteral blockage. In each instance the drug was stopped immediately and within twenty-four hours after the attack none of the patients offered any symptoms or laboratory evidence of any urinary tract disturbances. Recovery occurred in all of the above cases. The fifth patient,¹⁰ a thirty-year-old male, suffering with subacute bacterial endocarditis, received 14 gm of the drug during the first three days of treatment, with no apparent untoward effect. On the fourth day he was given 25 gm (sulfamerazine sodium) intravenously over a thirty-minute period. A free drug level, taken one hour after the infusion, was 106 mg per 100 cc of serum. The first voided specimen of urine thereafter contained many drug crystals and innumerable red blood cells. With the exception of the finding of occasional red blood cells in the urine throughout the next forty-eight hours and the partial suppression of urinary output for several days, there was no other evidence of renal damage. After five days the patient was again given sulfamerazine by mouth with no further urinary disturbances. The patient finally died and sections of the kidneys were examined and no renal damage was found which could be attributed to the drug.

Dermatitis

Skin rashes, developing during sulfamerazine treatment, were encountered in twelve patients (3 per cent). The rash was scar-

ltuniform in four and maculopapular or morbilliform in the others. These eruptions were observed in only two cases before the seventh day of therapy, in these they appeared on the fourth and fifth days respectively.

Nausea and Vomiting

In this series there were five patients (1.3 per cent) in whom nausea and vomiting occurred which we attributed to sulfamerazine. There were cases with vomiting before the drug was given which have been excluded, but in these the vomiting usually ceased after the infection was brought under control. In none of the patients with nausea and vomiting following the administration of sulfamerazine was it necessary to stop chemotherapy because of this toxic effect.

Blood Disturbances

Nine patients (2.3 per cent) developed leukopenia (less than 4000 leukocytes per c mm) between the sixth and twelfth day of treatment with sulfamerazine. In two the total white count returned to normal, although the drug was continued, whereas in six the total white count became normal soon after the withdrawal of sulfamerazine. The ninth patient was the one with subacute bacterial endocarditis mentioned previously, who received massive dosage of the drug and developed a thrombocytopenia as well as a leukopenia. A biopsy revealed a generalized hypoplasia of the bone marrow, although within two weeks after the drug was stopped the peripheral blood picture returned to normal.

Drug Fever

A diagnosis of drug fever was made in eight patients (2 per cent) receiving sulfamerazine. The fever in these cases was encountered between the fifth and fourteenth days of treatment.

Mental Manifestations

Although it is often difficult to determine whether certain neuropathologic changes are due to the drug or the disease we

have made the diagnosis of drug psychosis in four patients (1 per cent) In two of these, the mental symptoms subsided promptly after the drug was stopped, whereas in the others the mental changes gradually cleared, although the drug was continued

SUMMARY AND CONCLUSIONS

Sulfamerazine has been used in the treatment of 400 patients with a variety of acute infections From a pharmacologic standpoint, it appears that sulfamerazine is a more satisfactory drug than sulfadiazine in that higher blood levels are attained more rapidly and sustained longer by sulfamerazine than by similar amounts of sulfadiazine Thus, it is possible to maintain a given concentration of drug in the blood with smaller amounts of sulfamerazine than sulfadiazine Likewise, this feature of sulfamerazine may prove it to be superior to sulfadiazine as a *prophylactic agent* Furthermore, the rapid absorption obtained with sulfamerazine frequently makes the parenteral use of the drug unnecessary

The therapeutic results obtained with sulfamerazine in the cases of pneumococcal and meningococcal infections are comparable in every respect with the results obtained by us with sulfadiazine In the other conditions in which sulfamerazine was employed the limited number of cases involved prevents a definite comparison, although it appears that sulfamerazine is as effective as sulfadiazine in the various infections in which it was used¹⁹

In general, the toxicity of sulfamerazine is low and is no greater than that of sulfadiazine Gross hematuria, occurring in four patients receiving routine sulfamerazine treatment and in one given massive intravenous therapy, indicates that the drug may cause urinary tract disturbances. It is possible that some of these urinary tract complications might have been prevented or minimized had we employed medication with alkali^{20, 21} At least, the fact that urinary complications occurred makes the routine use of alkalis advisable

It appears that sulfamerazine, by virtue of its pharmacologic behavior, therapeutic efficacy and low toxicity, offers definite advantages over sulfadiazine and is worthy of extensive clinical trial

THE DIFFERENTIAL DIAGNOSIS OF ACUTE ABDOMINAL CONDITIONS*

W OSLER ABBOTT M.D., F.A.C.P.†

It is a natural instinct with all of us on seeing an acutely ill patient to leap for a diagnosis that no time may be lost in beginning treatment. Under such circumstances it would be absurd to set about the taking of a long formal history, for in many instances the patient himself cannot give it and the friend who brings him does not know it. Nevertheless, without system of some sort we will too often find ourselves in that embarrassing position of having the abdomen open but no lesion discoverable to account for the patient's condition. The problem therefore boils down to the question of the essential minimum. What question, what studies will yield the maximal diagnostic evidence with a minimum of wasted time and effort? What are the key points that identify the pathological process and the organ involved by it?

EXAMINATION OF THE PATIENT

I. A Consideration of Symptoms

The primary symptoms presented by acute abdominal conditions are (a) pain of four primary types, (b) distention or the evacuation of contents by mouth, bowel, bladder, or vagina and (c) systemic symptoms such as fever, prostration and dyspnea.

(a) ACUTE ABDOMINAL PAIN—Acute abdominal pain is ordinarily caused (1) by ischemia of muscle tissue, (2) by occlusion of a hollow viscus, (3) by serosal irritation, or (4) by stimulation of peripheral nerves. Since different organs and different disorders yield different types of pain and since the pains may commonly be distinguished on the basis of intensity, duration, location and radiation, one from another, their identification is important.

* From the Medical Clinic, Hospital of the University of Pennsylvania.

† Assistant Professor of Medicine, School of Medicine, University of Pennsylvania. Ward Physician, Hospital of the University of Pennsylvania.

Ischemic pain is typified in the body by the pain of a coronary occlusion. It is of great intensity, continuous in duration and fixed in position. In the abdomen such pain results from the cutting off of the blood supply to muscle but not to glandular or parenchymal tissue. Strangulation of the intestine by a hernia, a volvulus or an intussusception produces it most frequently but occlusion of a branch of the mesenteric blood supply by a thrombus or embolus must be considered when conditions favor the occurrence of such accidents. In my experience, mesenteric occlusions have most commonly happened a few days after a large coronary occlusion that has led in turn to the formation of a friable mural thrombus in the heart chamber.

Colic is the pain originating from contractions occurring in an occluded hollow viscus. It is intense while it lasts but comes and goes recurrently. Its location is ill defined in organs with a mesentery such as the small intestine, but is well defined in those organs having retroperitoneal surfaces such as the ureters or the flexures of the colon. A colicky pain therefore suggests an occlusion of the biliary tracts, the ureters or the alimentary canal.

Serosal irritation causes persistent pain localized, if the parietal peritoneum is involved, and exaggerated by movement of one surface upon another as in pleurisy. Therefore, the pain of a perisplenic inflammation is exaggerated by respiration. Infections above or below the liver are commonly caused by the localization of pus resulting from a ruptured peptic ulcer or an empyema of the gallbladder. In either case the inflammation is severe enough to stop diaphragmatic movement on that side. An infarct of the spleen, however, gives a pain closely simulating a left basal pleurisy. The strapping that would relieve the pleurisy accentuates the splenic pain, however, by increasing the diaphragmatic excursion. Acute abdominal distress from serosal irritation is generally accompanied by fever.

Nerve pain if limited to the abdominal wall is usually of a constant grade of intensity punctuated by severe lancinating exacerbations that radiate along the distribution of the nerve involved. The patient often refers to it as a "burning" pain. Typical is herpes zoster. When the pain precedes the eruption it is most important to determine that it is in the abdominal

wall and not originating in the underlying viscera. If a supine patient tightens the abdominal wall by lifting his head and his feet from the table the tenderness of a visceral lesion to palpation will be diminished by the protection of the tight muscle, but the tenderness of a neurogenic lesion will remain unabated. Disorders that give not only peripheral root pain but also disturbances of visceral motility, such for example as tabes dorsalis, are far more difficult to distinguish from visceral pain on abdominal examination alone. Unless a complete physical examination has revealed the pupillary and reflex changes of neural syphilis, one might easily be led into the error of operating. It is rare but not impossible that other neurological lesions be mistaken for acute visceral disorders. I have seen a man's appendix removed because the first hyperesthesia of oncoming poliomyelitis chanced to be in the right lower quadrant of his abdomen.

When the acuteness of a man's illness limits the taking of a history, the value of exact information on the intensity, quality, duration, location and radiation of the pain cannot be exaggerated.

(b) THE PROBLEM OF EVACUATION.—This problem ranks next to that of pain in acute conditions. Is there a history of distention, of obstructed flow from the bowel, the biliary tract, the bladder or the vagina, or is there a reverse flow in the digestive tract with vomiting? Obviously the distention will be related to the volume evacuated by the viscus. Obstruction of the common duct may render the liver and occasionally even the gall-bladder palpable. Obstruction of the intestinal tract may grossly distend the whole abdomen. So much is obvious, the confusions arise when the obstruction is partial. A story of frequent small micturitions may suggest not only a small irritated bladder but a distended, almost obstructed organ. The story of an effectual enema or a bowel movement is no denial of an intestinal obstruction, for the bowel distal to the lesion may contain considerable amounts of feces. The character of the discharge whether mixed with fresh blood from a low lesion or with digested blood from a high lesion, the appearance of foreign bodies, kidney stones in the urine, gallstone in feces, the presence or absence of bile in urine or vomitus—all are points that narrow the differential diagnosis.

(c) **THE SYSTEMIC RESPONSES**—The systemic symptoms are the third major consideration in the history. The presence of tachycardia, prostration and shock may be important differentials. Their significance will be considered under separate headings below.

2 Physical Signs

The physical signs presented by the patient may be local and correlated with the lesion itself, or generalized.

(a) **LOCAL SIGNS**—The local signs of importance in examining a patient with an acute abdominal condition are of course tenderness, whether generalized or localized, involuntary rigidity, and the presence or absence of a mass. If a mass is felt, its size, shape and the location in the abdomen give an inkling as to its origin. Movable masses migrate to the midline as they enlarge in the lower abdomen and from the midline in the upper abdomen. Nevertheless, because the anteroposterior diameter of the abdominal cavity is least in the midline above the promontory of the sacrum, that part of the mass extending toward the midline may be more easily felt.

The two least used of the valuable signs, however, are inspection of the abdomen for visible peristalsis, particularly that of gastric or colonic origin, and auscultation of peristalsis. The latter requires much study if full value is to be derived from it, but if given attention, it will yield most valuable information.

(b) **GENERALIZED SIGNS**—The generalized signs are not only the temperature, pulse and blood pressure, which give the first indication of the systemic reaction of the patient to his illness, but the rapidity with which metabolic imbalances follow abdominal catastrophe necessitate the observance of other indicators.

Dehydration in a vomiting patient may be judged by the turgor of the subcutaneous tissues. The great fluid reserve of the body is the extracellular interstitial fluid. As that is depleted the elasticity of the tissue beneath the skin is lost and a fold pinched up on the forearm fails to flatten out promptly, as though the skin were turned to putty. If dehydration increases the intravascular fluid reservoir diminishes. *Decreased blood volume* is early suggested by a failure of the veins over the back

of the hand to fill promptly and the nail beds become cyanotic from capillary stasis. As this is the step preliminary to *shock*, it is of vital importance to recognize it. When shock has become established the characteristic rapid "thready" pulse appears, the "thready" character being due to the low blood pressure.

Another metabolic change suggested by physical signs is related to the acid-base balance. If vomiting is causing loss primarily of gastric acid, the ensuing alkalosis will be suggested by Chvostek's signs—the twitch of the face caused by striking the region of the seventh nerve in front of the ear or by Trousseau's sign—the carpopedal spasm that results when the blood pressure cuff is kept for a few minutes on the arm.

3 Basic Laboratory Data

The basic laboratory data in these cases should include the *white blood cell count* for the identification of infection, the *hemoglobin* as an estimate of hemorrhage and sometimes of hemoconcentration, the determination of the *urine specific gravity*, *urine sugar* and *urine blood cells* whether red or white. If the patient is vomiting, a specimen of blood should be analyzed for chlorides, protein and carbon dioxide. A *roentgenogram* of the whole abdomen is advisable with the patient supine and if possible with him erect. The ruling in or out of (a) the presence of air under the diaphragm which often occurs when a peptic ulcer has perforated, (b) the ladder pattern of an obstructed intestine, (c) fluid in a distended inactive intestinal loop, (d) loss of psoas shadows suggesting retroperitoneal disease, and (e) calcification or displacement of organs is all-important. In short, the scout film is an invaluable diagnostic aid.

CONDITIONS ARISING FROM DIFFERENT ORGANS

The preliminary consideration of the symptoms will often identify not only the nature of the process but by its character and location may show from which organ it originates. Let us now consider the acute catastrophes most likely to arise from each organ. It is by acquiring the habit of such an orderly process of mind that we are saved from jumping to the most obvious rather than to the most probable diagnosis.

1 Peritoneal Cavity

The peritoneal cavity rarely becomes involved in acute conditions with antecedent localized symptoms. Pneumococcal peritonitis in girl children is an exception. In adults, the rupture of an *ectopic pregnancy* may infrequently fail to give localized symptoms before the peritoneal cavity fills with blood. I have twice seen the spontaneous rupture of *mesenteric vessels* into the peritoneal cavity in old arteriosclerotic men. When rapid diffuse hemorrhage into the peritoneal cavity does occur, generalized tenderness of the abdomen without rigidity and often with accelerated peristalsis is apt to be superimposed upon the symptoms of severe hemorrhage from any cause.

2 Gastro-intestinal Tract

The gastro-intestinal tract is the site of *strangulations*, *obstructions*, perforations, hemorrhages and infections producing acute conditions.

STRANGULATIONS—Strangulation gives rise to severe unremitting pain, but, because it is usually associated with obstruction of the intestine, waves of colic cause recurrent intense exacerbations. *Hernias* into the inguinal, femoral or umbilical ring cause the great majority of strangulations. These are commonly palpable. Second in frequency are the internal hernias caused by bands and adhesions and peritoneal pockets. They are rarely palpable. Far less frequent, save in children, are *intussusceptions*. *Volvulus* is the least frequent of the major causes.

The distinction between intestinal strangulations and simple obstruction is of the utmost importance since strangulations require immediate surgery while simple obstructions, if severe, may need days of preparation before an operation may safely be performed. The pain of a simple obstruction ceases almost completely between waves of colic while that of a strangulation is maintained at a high level of intensity. The tenderness of a simple obstruction is generalized and that of a strangulation is localized. The colic of simple obstruction is stopped by 10 mg of morphine sulfate subcutaneously. The pain of strangulation is rarely stopped by such a dose. A simple obstruction may take several days to kill the patient. The symptoms of a strangulation may reach a lethal intensity in twenty-four to thirty-six hours.

OBSTRUCTION OF THE INTESTINE.—Obstruction not only yields the colicky pain described but evidence of interruption of the flow, dimming back of the contents and reversal of the current

The flow of feces is cut off from its source. A bowel movement may occur or one enema may be effectual depending on how much feces lies distal to the blockage, but this should not hide the fact that an obstruction has occurred. Distention begins simultaneously in the region above the obstruction and in the stomach, the intervening length of intestine becoming distended as time goes on. Peristalsis is first increased in frequency and intensity, then in pitch, then the frequency diminishes and finally before peristalsis disappears it is infrequent, but has the high metallic tone of a plucked banjo string. Gradually all sounds lose intensity until a "silent belly" results. In this condition, rolling the patient on his side produces sounds like liquor bubbling out of a demijohn.

Fullness, belching, nausea, vomiting and fecal vomiting appear in rapid succession from the onset.

This picture is usually clear-cut if the occlusion is complete, and of mechanical origin. The so-called paralytic obstruction or ileus should be included here, however, because intestinal obstruction is a "functional" diagnosis. Anything that prevents the passage of content from mouth to anus leads to death whether the cause is mechanical, "paralytic," "inflammatory," or otherwise. Any condition that stops intestinal flow is therefore significant in diagnosing obstruction. The important point is neither to mistake a functional obstruction for one of mechanical origin, or vice versa, since the therapy is wholly dissimilar, nor to focus attention on the obstructive syndrome and fail to note the primary cause. Patients with renal stones, with Addison's disease and with azotemia have been operated on for intestinal obstruction. It is true the gut was obstructed but the obstruction was wholly functional in character.

Fever and leukocytosis appear early in strangulated obstructions but late in simple obstructions. Laboratory studies show (a) concentration of the blood, (b) hypochloremia and (c) hypoproteinemia. If the obstruction chances to be at or near the pylorus, alkalosis is indicated by a high plasma carbon dioxide.

The x-ray is very valuable in showing the distribution of gas in the intestine which not only confirms the diagnosis but occasionally helps to localize the lesion. Intestinal intubation, which is indicated in most nonstrangulated cases, makes possible the injection and subsequent withdrawal of an opaque medium for roentgenograms. By this means the surgeon operates with a clear idea of what he will have to do.

PERFORATIONS—Perforations of the digestive tract occur from different lesions in the following order of frequency: *appendicitis*, *duodenal ulcers*, *gastric ulcers*, *colon carcinomas*, *colon diverticula* and *Meckel's diverticulum*. The diagnosis is often suggested by the antecedent symptoms, but when a perforation occurs suddenly it produces the most intense form of serosal irritation pain. This is particularly true of the gastric and duodenal lesions and in any case the pain is proportional not only to the irritating quality of the juice released into the peritoneal cavity but to its volume. Thus a gastric ulcer perforating when the stomach contains 300 to 400 cc of highly acid liquid produces far more abrupt and intense symptoms than a colonic diverticulum leaking out a few drops of feces. Tenderness occurs promptly and is localized in proportion to the volume of "spill" and to the drainage gutters of the belly. Half a pint of gastric contents may finally collect in the rectovesical pouch and tenderness may then involve the whole abdomen. Boardlike rigidity results, accompanied by the systemic indications of shock. The bacteriostatic action of acid gastric juice renders the factor of infection less than in the case of a colonic perforation. The latter begin in a less fulminating manner, but the symptoms increase in severity as the peritonitis spreads.

Whenever there has been a perforation, fever and leukocytosis may be expected, but one of the most useful findings, if present, is the x-ray demonstration of gas under the diaphragm in a film taken with the patient standing.

SEVERE HEMORRHAGE—Severe hemorrhage from the digestive tract occurs in a descending order of frequency from *duodenal ulcers*, *gastric ulcers*, *gastric cancers*, *esophageal varices*, *Meckel's diverticulum*, and, finally, from *benign tumors* of the intestinal wall. While right-sided colonic cancers often manifest themselves first by the production of anemia, it is rare

for one to gush blood as the above named lesions do. It is even doubtful whether gastric cancer deserves the position given it, for while hematemesis is often the first symptom, it is rarely a sudden bleeding capable of prostrating the patient.

Duodenal ulcers stand so far in the lead that any patient passing tarry stools and vomiting blood may be assumed to have a duodenal ulcer till proved otherwise. Antecedent evidence of hepatic cirrhosis will suggest esophageal varices. Age, weight loss and a supraclavicular lymph node on the left will suggest a gastric cancer, but the problem becomes difficult when tarry stools are passed by a young man who does not vomit blood or who, on gastric lavage, has no blood in his stomach. The chances are still in favor of its being a duodenal ulcer but the possibility of a Meckel's diverticulum must be seriously considered. If the bloody stools are reddish rather than tarry, it may be safer to give the patient a swallow of barium and fluoroscope him (without palpation) since a Meckel's diverticulum should be operated on and a bleeding duodenal ulcer should not.

INFECTIONS—Infections of the digestive tract deserve a word also, for while acute dysenteries and cholera are apt to appear in epidemic form if at all, sporadic fulminating "food poisoning" occurs not infrequently. This is commonly caused by an overwhelming dose of staphylococci. A baker coughs into a batch of cream puff filling and puts it in a warm place. Some time later he fills a "shell" with what by then may be a massive culture of the organism. The result is a widespread necrosis of the intestinal mucosa. One sporadic case of this sort may be a real diagnostic problem.

3 Biliary Tract

Biliary tract lesions that are acute are most commonly caused by (*a*) stones in the cystic duct (without jaundice), (*b*) stones in the common duct (with jaundice) and (*c*) empyema of the gallbladder with the fever, leukocytosis, local pain and tenderness that would characterize any abscess.

Acute disorders of the gallbladder and bile ducts affect women more often than men, they rarely occur before thirty years of age and are not common before forty, they are associated with a sense of flatulence and often intense belching and nausea, but perhaps most characteristic is the reference of the

pain. As a rule this centers over the right hypochondrium, radiating either "through" or "around" to the angle of the right scapula. Much has been said of right shoulder pain in biliary tract disease, and it is true that occasionally a reference to the right trapezius ridge does occur but this is less notable for its frequency than for its interest when it occurs. The frequency with which the symptoms of gallbladder disease suggests those of an active ulcer leads me to emphasize one other small point. An ulcer patient presses on the sore spot for relief. A gallbladder patient may find even the contact of clothes intolerable. Finally, however, it is jaundice that stands out as of chief importance. Gallbladder colic is not associated with jaundice, for the common duct is clear. If jaundice occurs the obstruction is between the liver and the intestine, and carries with it the threat of serious hepatic damage.

4. Urinary Tract

Acute urinary tract conditions are less likely to be mistaken for other things because of the radiation of pain to the groin and often to the testicles in men, and because of the blood in the urine though sometimes in microscopic amounts. In women, however, the reference of pain may at times confuse the condition with diseases of the fallopian tubes. It is also worth noting that reflex digestive symptoms promptly set in when a stone enters a ureter, so that occasionally patients with ureteral calculi are mistakenly admitted for intestinal obstruction.

5. Female Genitalia

Acute disorder of the female genitalia are rarely mistaken for other conditions, because of their antecedent symptoms. Occasionally a girl who does not know that she is pregnant suffers a spontaneous rupture of an ectopic pregnancy or in older women a subserosal myoma or ovarian cyst becomes twisted on its pedicle with strangulation. On the whole, however, the nature of the acute conditions is usually fairly clear.

6. Pancreas

The pancreas is an infrequent source of acute illness, but when acute hemorrhagic pancreatitis occurs, its diagnosis is by no means easy. The severe shocking pain going through to the back and the unmistakable evidence that a major catastrophe

has overtaken the patient cannot be missed, but the perforation of a gastric ulcer into the lesser peritoneal cavity or an acute cholecystitis may be strongly simulated. This is especially true when one considers the small but important percentage of pancreatitis cases which simultaneously present a gallstone in the common duct. Were operative intervention helpful in all these conditions, an exact diagnosis would be of little importance, but surgery offers little to the acute pancreatitis patient, and there are many who would avoid immediate operation on these patients if they could be selected with certainty.

One special test is almost diagnostic here but is so dependent for its accuracy upon the experience of the technician that few hospitals hold it available. Indeed few hospitals see enough acute pancreatitis to allow the laboratory to gain any experience, but when it can be done the blood amylase determination is diagnostic. For the few hours succeeding the onset of an attack the amylase content of the blood is very high. Later it falls without alleviation of the condition and means nothing. The test therefore is of most value at the stage of the disease when information is most needed.

7 Nervous System

Neurological lesions have already been mentioned in the discussion of pain but should be re-emphasized, since they are rare enough to be easily overlooked. The abdominal pain is in the belly wall rather than in the viscera in herpes zoster, intercostal neuralgia and the girdle pains of tabes, but the extrinsic nerves of the viscera may carry in from parts remote from the peritoneal cavity, impulses that disrupt visceral function. After brain operations, including those on the pituitary gland, acute perforating or hemorrhagic ulcers of the stomach and duodenum occasionally form. Attacks of migraine may occur simulating cholecystitis. Epilepsy in rare instances affects the digestive tract alone with such violent colic as to almost reproduce the intussusception appearing in the small intestine of a monkey during appropriate cortical stimulation.

NONABDOMINAL CONDITIONS

Finally, there are those conditions manifesting themselves in acute abdominal symptoms that are of systemic rather than local origin.

Metabolic Diseases

Amongst the metabolic diseases we must remember that *diabetic acidosis* in the young patient is often accompanied by right lower quadrant pain, nausea, leukocytosis and fever. The smell of acetone on the breath of such a patient may save an operation that is not only needless but under the circumstances harmful.

Acute *porphyria* is rare enough to pass unrecognized particularly if it is the type without "port-wine" urine. The intensity of the colic and absence of diarrhea may suggest intestinal obstruction, but the subnormal mentality usually points to porphyria and the diagnosis may be clinched by acidifying the urine and seeing it fluoresce red under an ultraviolet lamp.

Crises of *Addison's disease* with rapidly developing distention have been mistaken for intestinal obstruction, and where the pigmentation has been overlooked, the low blood pressure has been thought to be a part of shock.

Hematologic and Cardiovascular Disorders

A hematological condition falling within this field is *sickle cell anemia*. The abdominal pains incident to this disorder have led also to needless appendectomies, though here again if one but suspects the possibility, a distinguishing point is ready at hand. Since the attack of sickle cell anemia is an acute hemolytic process the reticulocyte count is characteristically elevated.

Among cardiovascular disorders that are confused with abdominal disease, *myocardial infarction* has received proper emphasis. There are cases of coronary artery occlusion in which the pain is referred to the epigastrium but the electrocardiogram, particularly with chest leads, is now so accurate and so accessible that the diagnosis should not be long in doubt.

Intoxications

Finally, intoxications must not be overlooked. These may be accidental and range from *lead poisoning* to "*black widow*" *spider bite*. To think of the possibility is generally to discover the diagnosis. There may also be criminal poisonings. The *arsenic* "insurance murders" of a few years ago were promptly recognized as such. And in conclusion, one must consider the effect of "*intoxication*" in the ordinary sense. I re-

member a lumberman admitted with what seemed clearly a perforating gastric ulcer. Two hours later the resident was sure the patient had a stone in the cystic duct. Next day he passed bright blood by bowel and had an excruciating pain over the cecum. That night he was heard screaming in the toilet and wedged in his anal sphincter was a triangular piece of tin roughly 2 cm on each side. When confronted with it he denied any recollection of having swallowed it, but admitted that the night before the first attack he had celebrated with some friends until morning.

TROPICAL DISEASES OF CONCERN TO THE HOME FRONT

WILLIAM HARVEY PERKINS, M.D., Sc.D.*

YEARS of intelligent planning by the health services of the United States has resulted in the development of formidable defenses against importation of many tropical and exotic diseases. Vigilance within the continental boundaries of this country has eliminated or brought under practical control many diseases that formerly existed here but still occur in other countries. Awareness of the potential dangers from without on the part of our general medical profession has not been developed equally with that of the few who know on how narrow a margin we operate against the growth and spread of the so-called exotic diseases that menace us.

The home front is in danger from many diseases, largely of bacterial or parasitic origin, that can and might increase here unless the barriers remain effective or new ones are built against new threats.

An obligation is assumed by every practitioner to notify the health authorities of certain diseases coming under his observation. State and municipal health departments, the United States Public Health Service and the medical services of our armed forces depend largely for their knowledge of diseases existing among us on the accuracy of information supplied them by the civilian doctors. The completeness of this information rests largely therefore on the diagnostic acumen of the private practitioners and the degree to which they give notice of the reportable diseases among their patients.

Freedom from the great epidemics of former times and the little opportunity given to the doctors in this country to know about them through study or experience has resulted in an almost contemptuous attitude toward them. World War II has

* Dean and Professor of Preventive Medicine, Jefferson Medical College, Attending Physician, Jefferson Medical College Hospital

jolted us into consciousness of the fact that the epidemics and plagues of other countries are today approaching perilously near our own shores. There is already evidence that some have entered our borders and are no longer only theoretical invaders. Straggling remnants of the great plagues of Europe and the Orient in certain areas of this country are evidence of their presence here in times past, that they cannot resurge in serious proportions is not assured us.

The war is a medical emergency in the United States, not only because of war casualties and the problems of ordinary medical care of millions of our citizens now in service at home and abroad but because the conditions of war have disturbed the balances of control that have limited the prevalence and spread of the little-known and long-feared world plagues.

A realistic study of the tropical diseases reveals the seriousness of the present situation. In general we are faced with the possibility that three groups of tropical diseases can and may assume serious proportions within this country. These groups are (I) those already present to some degree among certain groups of our population, (II) those formerly prevalent here even in epidemic proportions but that have not been recognized or reported in the United States for a number of years or decades, (III) diseases of endemic or epidemic occurrence in other countries that have never been recognized within our continental boundaries.

Familiarity with the tropical diseases has become an essential obligation of every practitioner in this country, he must know them by name, anticipate their occurrence, be informed on how to recognize them and know at least something of their care, treatment and control.

I TROPICAL DISEASES CURRENTLY PRESENT IN THE UNITED STATES

Malaria

The story of malaria is the story of the *Anopheles* mosquito. Within the limits of the factors that determine the survival of the parasite and the insect host, malaria is possible anywhere that this mosquito exists. Within the United States, its geographic distribution is widespread. Malaria in one form or another has always been present in this country and has been

a disease of great medical and economic importance. The physicians of the past generation were greatly concerned with it in areas in which it is now nonexistent or appears so rarely that it is considered of little significance. The typho-malaria of the earlier years of this country's medical history is evidence of the confusion and difficulty in differentiating two diseases of heavy prevalence during those times.

The changing picture in the prevalence rate of malaria in the various states of this Union can be ascribed with little hesitation to the influence of two factors: (1) antimosquito campaigns, whether directed primarily against the malaria-carrying mosquito or against mosquitoes generally as nuisances, and (2) general socio-economic improvements that have changed our environment and living conditions in such a manner as to militate against the factors favorable to the persistence of malaria.

Control Measures—Antimalarial measures against all factors responsible for the propagation of the mosquito and the spread of the plasmodium is the only effective approach to the control of this disease. Recognition, diagnosis and treatment of cases of malaria are not to be minimized but they cannot alone be effective against a disseminating mechanism as widespread as mosquito transmission. The part played by the physician in the sterilization of all malaria patients under his care removes a certain part of the hazard but cannot be counted upon for eradication of the disease from the population.

In a peacetime American community mosquito control is reasonably accomplished. It involves the expenditure of considerable sums of money and much may be wasted in ineffectual measures unless those who accept responsibility for mosquito control are well informed on the details. Specifically, this means a knowledge of the species of mosquitoes to be eliminated, including their breeding habits and the special geographic, meteorologic and social factors involved, as well as an understanding of the changes in the environmental conditions most likely to be detrimental to the mosquito population.

Thus, where time is of little concern, measures such as drainage, diversion of streams, land clearing, oiling and the spreading of larvacides are the most effectual far-reaching procedures to be adopted.

When the menace of malaria in a community is imminent and serious the immediate control measures must become centrifugal,

ie, they must begin with the individual and progress outward through the community. Such measures will be early diagnosis and adequate care of malaria patients, suppressive (prophylactic) treatment of those exposed, mosquito bars and nets for individuals, screening of windows and homes, and finally, household and community attacks on domestic and neighborhood larva-breeding places such as cisterns, pots, drains, and other water-containers, and out-door pools, ponds, ditches, low-lying areas and other natural or artificial collections of water.

Prophylaxis—Malarial infection cannot be prevented in the individual by antiparasitic drugs. The prophylactic use of quinine cannot prevent infection by the invasive stage of the protozoa but it can destroy plasmodia in the blood at other points in their human cycle and thus act as an inhibitor of the full clinical manifestations of the disease. This is expressed in the new belief that quinine prophylaxis is suppressive treatment rather than preventive.

Treatment—Effective treatment of malaria is best obtained at this writing by the combined use of quinine, atabrine and/or plasmochin. Each of these drugs has specific effects on the developmental forms of plasmodia. In general, quinine and atabrine destroy the schizogonic forms of benign, quartan and aestivo-autumnal malaria parasites and the sexual forms of tertian malaria but are less effective against the gametocytes of quartan and aestivo-autumnal plasmodia. Plasmochin on the other hand produces no effectual results against any of the asexual forms of any types but destroys the sexual forms of all types. None of the three drugs mentioned will destroy sporozoites. Because of this fact infection can occur even in the presence of these substances in the blood and it is for this reason that no known drug is considered to be a true preventive.

RECOMMENDED TREATMENT OF MALARIA (COMBINED USE OF QUININE, ATABRINE AND PLASMOCHIN)¹

1 Quinine sulfate, 10 grains (0.64 gm) three times daily after meals for two or three days, or until pyrexia is controlled. Then give

¹ Acknowledgment is made of the liberal use of the recommendations of the Subcommittee on Tropical Diseases of the National Research Council as presented in the notes published by the United States Naval Medical School, October 1942, and Circular Letter No. 33 from the Office of the Surgeon General, War Department, February 2, 1943.

2 Atabrine, $1\frac{1}{2}$ grains (0.1 gm) three times daily after meals for five days. Then after two days without antimalarial medication, give

3 Plasmochin, $\frac{3}{20}$ grain (0.01 gm) three times daily after meals for five days, except for the debilitated patient, who should receive only two doses daily. Discontinue if toxic symptoms occur.

Never give atabrine and plasmochin concurrently

When quinine is not available use atabrine for seven days and then after two days' interval use plasmochin.

When atabrine is not available use quinine for seven days and then use plasmochin.

In comatose patients or those with vomiting, who are unable to take medicine by mouth, give quinine dihydrochloride intravenously as 5 to 10 grains (0.3–0.6 gm) to 100 to 200 cc of sterile normal saline solution. Give this amount over a period of about thirty minutes. Repeat every eight hours until the patient can take quinine by mouth.

Atabrine dihydrochloride may be substituted for quinine in these cases but is to be given intramuscularly in alternate buttocks in doses of 0.2 gm. Repeat at eight-hour intervals.

Amebiasis

American plumbing has saved this country from a serious, widespread incidence of amebic dysentery. Surveys indicate that something like 10 per cent of the population of the United States harbor *Endamoeba histolytica*, the causative protozoan parasite. That this has not resulted in more outbreaks of severe epidemics is a triumph of sanitary engineering and a tribute to the high-level food habits of the population.

Endamoeba histolytica always produces lesions in its human host, but for unaccountable reasons seldom results in this country in the serious dysenteric form of the disease. How much disability results from this infection is not known. Many of the undiagnosed intestinal disorders that swell the sickness rates of industrial reports on absenteeism may be of this origin. Failure to recognize the cause is due largely to unawareness of medical practitioners generally that the menace exists in any important proportions.

Granting that there will be no let-down in our general sani-

tary standards, the burden of the control of amebiasis and amebic dysentery must rest almost solely on recognition of the disease.

The diagnosis of amebiasis is made by finding the parasite in the stools. The techniques of fecal examination are simple but the recognition of the pathogenic amebae is a matter for experts. Until physicians recognize their limitations and call upon those qualified to diagnose the vegetative and cystic stages of amebae in stool samples, they will continue to be overlooked and misdiagnosed, amebiasis will remain unrecognized and the disease will continue at its too-high endemic rate.

Treatment—Dysentery cases due to this organism, whether acute or chronic are best treated by intramuscular injections of emetine hydrochloride. It is administered in $\frac{1}{2}$ -gr (0.03-gm) doses twice a day for four to six days. Carbarsone in doses of 4 grains (0.25 gm) three times a day by mouth should be given concurrently with emetine but should be continued for one week. Following the week on carbarsone the patient should be placed on vioform (4 grains) or diodoquin (9 grains), by mouth, three times daily, for another week. Ineffectual treatment from such a course usually requires supplemental rectal instillations of carbarsone or chiniofon, the former as a retention enema at night, made up of 30 grains (2 gm) of carbarsone in 200 cc of a 2 per cent sodium bicarbonate solution and the latter as 60 grains (4 gm) of chiniofon in 200 cc of sterile water instilled per rectum. Each of these instillations should be preceded by a cleansing enema.

Bacillary Dysentery

The devastating prison and camp dysentery of former days has become a thing of the past in this country. Sporadic outbreaks of bacillary dysentery still occur when the commonly accepted food precautions have been permitted to lapse or, in some instances, where unforeseeable mass infection of food has occurred. The *Shigella* organism responsible for this disease must be carried directly or indirectly from the intestinal canal of a person harboring it to a susceptible individual. The chain of events in this transmission may be as direct as immediate contamination of fingers, food, or drinks by alvine discharges or as remote as contamination from dirty utensils and containers.

or by flies. For these reasons the propagation of *Shigella dysenteriae* depends on unhygienic habits of individuals, faulty food processing, the preparation and cooking of food under unsanitary conditions, and exposure of food and drinks (particularly milk) to conditions of temperature and moisture favorable to its growth.

Control Measures—It is assumed that military installations will continue their efficient policing of kitchens, mess halls and food-handling personnel that has been so effective in eradicating camp dysentery from our armed forces. The same degree of precaution should be taken by medical municipal and other authorities over all concerned with the preparation and serving of food and foodstuffs in public eating places. Proper sewage disposal under all conditions must continue.

In spite of all precautions, cases of bacillary dysentery will continue to appear. The circumstances under which they occur may often be difficult to determine, but if they are duly reported by physicians and the responsible health authorities are alert and active in their follow-up of the outbreak there can be no real danger of widespread dissemination of this disease. With little question, the continuance of any significant number of cases of bacillary dysentery in a community is an indictment of the medical profession, official and otherwise.

The principal duty of the practitioner is the diagnosis and treatment of his cases and, recognizing its nature, his participation in the control of the disease by placing the known cases on sanitary precautions.

Treatment—For immediate treatment sulfaguanidine is the most effective medication. Given in doses of 3.5 gm (52½ grains) every four hours, by mouth, day and night, sulfaguanidine will reduce the daily number of stools to five or less in a very few days. When it has done so, the drug is continued at the same dose at eight-hour intervals until the stools have been normal for four days. Failure of the case to respond after a week of such therapy is an indication to discontinue the use of this drug. Sulfthiazole or sulfadiazine in doses of 4 gm. (60 grains) every four hours, by mouth, may be substituted for sulfaguanidine if necessary.

The loss of fluids should always be replaced by an adequate intake, either by mouth or intravenously.

The stools and all clothing, bed-clothes and dishes used by dysentery patients should be sterilized by heat or chemicals

Dengue

The littoral of the Gulf States is an area of repeated occurrence of dengue and from Florida to Texas outbreaks of the disease have occurred in the last two decades that involved hundreds of thousands of the population

From the point of view of mortality, dengue is the least important of all epidemic diseases of the tropics, for it is not fatal. Viewed from the temporary disability produced by an attack, an epidemic of dengue is capable of producing widespread invalidism and incapacity for work not only during the attack but throughout a very uncertain period of convalescence.

Dengue is a virus disease, transmitted by the mosquito *Aedes aegypti*, and in this country probably also by *Aedes taeniorhynchus*. The patient is infective for the mosquito from any time between the few hours before the onset and the third or fourth day of the disease. The mosquito becomes infective for man about ten to fourteen days later.

The conditions for the accentuation of the disease to epidemic proportions are those that favor the increase in the mosquito population, enhancement of their chances of survival and their access to man, and the relative number of infected and susceptible individuals in the community.

Such a concourse of events has happened occasionally in the Gulf States and occurs repeatedly throughout the tropics.

The return of thousands of our military personnel from dengue-infested countries, some of whom may carry the active virus in the seven to nine days of the incubation period, will augment at least one factor favorable to an increased incidence here. Whether or not this can result in epidemic proportions cannot be predicted. It is certain, however, that no soldier returning to this country from endemic dengue areas should be permitted freedom among the general population until he has been under observation for the period of incubation and under conditions where the favorable mosquito carrier can not have access to him.

There is no specific preventive, treatment, or diagnostic test for dengue. The important problems connected with it are

or by flies. For these reasons the propagation of *Shigella dysenteriae* depends on unhygienic habits of individuals, faulty food processing, the preparation and cooking of food under unsanitary conditions, and exposure of food and drinks (particularly milk) to conditions of temperature and moisture favorable to its growth.

Control Measures—It is assumed that military installations will continue their efficient policing of kitchens, mess halls and food-handling personnel that has been so effective in eradicating camp dysentery from our armed forces. Dengue

The littoral of the Gulf States is an area of repeated occurrence of dengue and from Florida to Texas outbreaks of the disease have occurred in the last two decades that involved hundreds of thousands of the population

From the point of view of mortality, dengue is the least important of all epidemic diseases of the tropics, for it is not fatal. Viewed from the temporary disability produced by an attack, an epidemic of dengue is capable of producing widespread invalidism and incapacity for work not only during the attack but throughout a very uncertain period of convalescence.

Dengue is a virus disease, transmitted by the mosquito *Aedes aegypti*, and in this country probably also by *Aedes taeniorhynchus*. The patient is infective for the mosquito from any time between the few hours before the onset and the third or fourth day of the disease. The mosquito becomes infective for man about ten to fourteen days later.

The conditions for the accentuation of the disease to epidemic proportions are those that favor the increase in the mosquito population, enhancement of their chances of survival and their access to man, and the relative number of infected and susceptible individuals in the community.

Such a concurrence of events has happened occasionally in the Gulf States and occurs repeatedly throughout the tropics.

The return of thousands of our military personnel from dengue-infested countries, some of whom may carry the active virus in the seven to nine days of the incubation period, will augment at least one factor favorable to an increased incidence here. Whether or not this can result in epidemic proportions cannot be predicted. It is certain, however, that no soldier returning to this country from endemic dengue areas should be permitted freedom among the general population until he has been under observation for the period of incubation and under conditions where the favorable mosquito carrier can not have access to him.

There is no specific preventive, treatment, or diagnostic test for dengue. The important problems connected with it are

therefore those of mosquito control and the diagnosis of the case. The former is adequately dealt with elsewhere.

Differential Diagnosis—Differential diagnosis is largely a matter of eliminating those conditions which it may simulate: influenza, malaria, yellow fever, relapsing fever, smallpox and the so-called denguelike fevers. Dengue has not the acute catarrhal symptoms of influenza, and its postorbital pains and pain near all large and small joints are far more intense than the generalized aching of influenza. The differentiation between yellow fever and dengue will ordinarily be made by the appearance of jaundice and severe albuminuria in yellow fever and the macular, peripherally-beginning eruption around the fourth day of dengue. In retrospect, the saddle-back temperature curve and the slow pulse may appear quite similar in both diseases. The absence of breakbone pains and time will differentiate the course of relapsing fever from dengue, while the leukocytosis and rash of smallpox will ultimately reveal the true nature of this disease. There is no practical way to differentiate the five-, six-, and seven-day denguelike fevers of the tropics from dengue until after the event. Even then, the ultimate course of the disease may make it possible for only a shrewd guess that it was not typical dengue.

Leprosy

This is a disease of practically all countries and deserves special consideration under Tropical Diseases only because of its present high incidence in tropical areas.

In the United States cases still continue to appear sporadically in the population. While many of our segregated cases at Carville, Louisiana, are importations from other countries there are some that undoubtedly have contracted and developed their infection within this country. How or in what manner their infection was acquired is entirely unknown. There is considerable evidence of familial prevalence.

There is a general feeling that the ease of contracting the disease varies in different areas. If this is substantiated an additional hazard is presented to our soldiers and sailors assigned to endemic areas. The indefiniteness of the incubation period, ranging as it apparently does from months to years, produces an at present insoluble problem in the matter of continental quaran-

time It would only be those with visible lesions of early leprosy who could justifiably be held for observation for any significant length of time

Diagnosis and Management—While the major point in diagnosis may be the finding of acid-fast organisms in smears from lesions and the reasonable demonstration that they are not *Mycobacterium tuberculosis*, the practical recognition of cases of leprosy must still rest on those capable of making a clinical diagnosis For this reason practitioners generally are admonished to suspect leprosy in all not readily diagnosed skin and peripheral nerve lesions and be willing to seek early consultative advice This is particularly true when skin lesions are combined with anaesthesia or paresthesia.

Leprosy is a universally notifiable and reportable disease The inability of the private practitioner to cope with the manifold problems aroused by the discovery of a case makes it imperative that he call upon the authorities for proper disposition of his patient. By the same token his responsibility is increased for the exercise of his greatest diagnostic skill in the diagnosis and handling of suspected cases.

Relapsing Fever

Tick-borne—Tick-borne relapsing fever is the only form of this disease encountered in the continental United States It occurs in the Southwest, particularly in the valley of the Colorado River and in California

The specific parasite, *Borrelia duttoni*, is transmitted in the American form of the disease by the soft-bodied ticks of the genus *Ornithodoros* These ticks breed in the habitats of rodents and bats, but on invading houses and huts behave much like bedbugs The spirochetes liberated from ticks gain entrance through any abrasion or lesion of the skin

Relapsing fever is at present a diagnostic problem only in the endemic areas of the Southwest Were all cases recognized or suspected soon after the onset of rapid rise in temperature, chills and generalized pains, the diagnosis would be readily made, for a blood smear at that time would reveal the causative agent. Delay in examination of the blood may result in negative findings, for the febrile attacks may terminate by crisis in five or six days and the spirochetes disappear from the per

spheral blood The enlargement of the spleen in this condition adds to the possibility of confusion with malaria

Recurrence of the disease after an afebrile period of four or five days may be the cause of the first suspicion that relapsing fever is being dealt with A blood smear at this or subsequent recurrences should confirm the suspicion

Louse-borne—Although the louse-borne European and African forms of relapsing fever are not known to exist in this country, there appears to be no good reason why they could not They are caused by spirochetes morphologically identical with those of American relapsing fever but transmitted by the body louse (*Pediculus humanus*) It may be premature to predict the possibility of the introduction of this strain to America and its establishment here Since the differences between the strains are so minor and because the body louse is prevalent in this country, the suspicion exists that, given a sufficient number of unrecognized cases and the proper concentration of susceptibles under conditions of lousiness, this potential importation may become actual

Control Measures—It is obvious from this brief discussion that prevention rests on recognition of the cases and personal and domestic hygiene Any personal or large scale measures against the tick or the louse will control the spread of relapsing fever

Filariasis

The presence up to very recent years of an endemic focus of this disease in and about Charleston, South Carolina, warrants consideration of filariasis among the tropical diseases now present in this country Although this focus may not now exist, cases having their origin in Charleston or elsewhere in the Western Hemisphere are reported from time to time in cities of the United States The presence of returned troops who have filariasis and are now in our military hospitals in this country is further reason for considering it under this category

Classical filariasis with elephantoid swellings is produced by the specific blood filaria *Wuchereria bancrofti* It is spread throughout practically all tropical areas of the world through its mosquito hosts, particularly *Culex quinquefasciatus*, *Culex pipiens* (China) and *Aedes variegatus* (Pacific Islands).

The necessary vectors are present in many areas of the United States and there is little reason to doubt that, given a sufficient number of infected individuals in a community where the proper mosquito host exists and the opportune season for the infection to become widespread in the mosquito population, secondary cases and even endemic foci might become established. The lesson of immediate importance to be learned from the epidemiology of this disease is that troops with filariasis returned from endemic areas must not be hospitalized in localities where potential mosquito hosts exist and that they must be prevented from being bitten by mosquitoes.

Diagnosis—Until the lymph blockage begins to reach the clinical stage, filariasis may be present without any symptoms. This symptom-free period is of variable length and may be sufficiently long to extend beyond the ordinary quarantine period for other infectious diseases.

The presence of unexplained swellings of any kind on any parts of the body of exposed individuals warrants a search for microfilariae in the peripheral blood. In this species, the microfilariae migrate at night so that the search by means of peripheral blood smears should be made around midnight.

Prevention and Treatment—There is no present known specific treatment for the disease but sulfadiazine has been recommended. Prevention involves every known measure for mosquito control.

II TROPICAL DISEASES FORMERLY BUT NOT NOW PRESENT IN THE UNITED STATES

Yellow Fever

The last recognized case of yellow fever in the United States occurred in 1905. Since that time the Gulf States have maintained a particularly sharp vigilance against its re-introduction from endemic areas in South America. The acceleration of travel by means of airplane has sharpened the precautions taken by the United States Public Health Service. This country is by no means removed from the danger of resurgence of this disease in epidemic proportions. Insofar as is known, the population of the United States has for many years been theoretically 100 per cent susceptible. The few persons in the Gulf States who may

have developed immunity prior to 1905 may be ignored. Within recent months many of our armed forces have received protective vaccination but for practical purposes these too need not be considered, for an unknown number have left these shores.

While it cannot be said with assurance that yellow fever is a potentiality wherever the vector (*Aedes aegypti*) of the virus exists, it can be assumed that epidemic yellow fever will not occur where this mosquito is not present. Historically, yellow fever has appeared in epidemic proportions throughout the southern and eastern Middle Atlantic coastal plains and it might possibly appear again.

Control Measures—Mosquito control and quarantine have been the measures responsible for the eradication of yellow fever from this continent. To these may now be added preventive immunization. Thus the prevention of this disease approaches the ideal, a potentially immune population, sufficient knowledge of the vector to enable its effective control, and efficient quarantine service both at the point of embarkation and debarkation of immigrants.

Diagnosis—It is impossible within the scope of this presentation to give adequate information regarding the clinical aspects of this disease and the measures necessary for its recognition and diagnosis. That it is an acute febrile disease characterized by jaundice, albuminuria, bradycardia and severe liver damage can hardly suffice. Treatment is only symptomatic and cannot be covered adequately here. There is moreover no diagnostic test readily available to practitioners or within the routine possibilities of most laboratories. Whenever suspected it should always be reported immediately.

It remains therefore only to point out that every fever with jaundice should be thoroughly investigated. Confusion is most likely between yellow fever, infectious jaundice (leptospiroid jaundice) and acute catarrhal jaundice. In the case of the latter, special difficulty may be encountered when added zeal on the part of a physician results in a positive test for yellow fever (mouse protection test) in a patient with catarrhal jaundice who has been previously immunized with yellow fever vaccine! There may be many such among our returning troops.

Plague

This acute infectious disease has, in the course of history, been present in almost all countries and left behind it rodents infected with *Pasteurella pestis*. This appears to be true in this country, particularly in the Central and Northern States west of the Rocky Mountains.

Strictly speaking, this disease should be included among those still present in the United States but the conditions under which the infection persists in the rodent population without other than a few accidental cases among humans makes it reasonable to discuss it here. This is particularly true in respect to the country as a whole, for the Eastern seaboard where it formerly appeared in such intense epidemic proportions is now, so far as known, free of even the rodent form. Conditions apparently exist on this continent which make its spread to the human population possible whenever the factors responsible for its transmission become favorable. As with yellow fever and cholera, the soil is ripe but the spreading of the seed has been prevented by active measures against it. The most effective measure has been rat control.

Epidemics of plague are usually of rodent origin. Infected rats, squirrels, marmosets or other rodents develop periodic epizootics. The rat flea transmits the causative agent, *Pasteurella pestis*, by its bite, to man. The primary bubo of bubonic plague is the regional lymph node swelling following the flea bite, septicemic plague is the blood-stream infection with the same organism, pneumonic plague is the secondary pneumonia developing in one of the previous two forms or resulting primarily in the lungs following inhalation of infected droplets from a contact case of plague pneumonia.

Control Measures—There is at present no alternative to the control of plague by antirodent and flea extermination other than by the supplemental use of plague vaccine. In the Far East, particularly in Java, and more recently in Africa, widespread use is made of Otten's attenuated living vaccine, while in India, China and most other threatened areas Haffkine's killed vaccine is used. In either case the consensus seems to be that annual vaccination is necessary and that periods of effective immunity longer than a year are not reliable or obtainable.

The reader must be referred to more exhaustive works for all of the detailed procedures involved in the protection of ships, warehouses and dwellings from infestation with rats and for the various insecticides and fumigants for the eradication of fleas.

The current speed-up in communications makes it imperative that there be no let-up in the splendid national and international quarantine agreements against the spread of plague. No country can afford to neglect the potential hazards of this devastating disease and continued concerted action by all nations is necessary for its control.

Cholera

The level of sanitation in the United States is almost complete assurance that this presently exotic disease could not gain a hold in any representative community of this country.

Cholera is so much a disease of massed populations under unsanitary conditions that only the most serious breakdown in our quarantine, and concurrent let-down somewhere in sanitary precautions would permit its introduction here.

Nevertheless, vigilance must be continued because of uncertainties brought about by the speed of travel and the consequent nearness of the Orient.

Control Measures—Aside from quarantine law enforcement and the maintenance and improvement of sanitation in some backward areas of this country, the best precaution against reintroduction of cholera into the United States will rest on individual hygienic measures and the use of protective immunization.

Cholera is the story of fecal contamination of food and water. The cholera vibrio is a water-breeder and can exist in any polluted water supply. Vegetables and fruits may readily become secondarily contaminated from impure water in which they are grown, washed or improperly prepared for eating. In endemic cholera areas no fresh fruits or vegetables should be eaten unless they have been thoroughly washed with clean water or antiseptic solutions such as potassium permanganate, or scalded. Fruits that must be peeled to be eaten are safe inside but may be contaminated outside, the act of peeling such an unwashed fruit may itself contaminate the edible interior.

Vaccination against cholera is effective but not lasting and

should not be depended upon for a period longer than four to six months. Usually an annual reimmunization is sufficient in those areas where the cholera season comes once a year.

The arrival of a cholera patient at our seaports or points of landing of airplanes from endemic areas is not an impossibility. The abrupt onset of diarrhea, vomiting, rice-water stools and dehydration should be sufficient impetus to make any physician in charge go into immediate action and look for vibrios in a hanging drop from the watery stool.

III TROPICAL DISEASES NEVER KNOWN TO HAVE BEEN PRESENT IN THE UNITED STATES

African Trypanosomiasis (African Sleeping Sickness)

The tsetse fly (*Glossina palpalis* and *G. morsitans*) is the only known carrier of the trypanosomes (*Trypanosoma gambiense* and *T. rhodesiense*) responsible for sleeping sickness. This fly is unknown outside of Africa and Arabia and for this reason alone trypanosomiasis could hardly be permanently introduced into this country.

Interest in African sleeping sickness in America centers around the likelihood of cases in the preclinical period of the disease being returned to the United States. Since this period varies from ten days to three weeks or more, this is a possibility.

Those concerned are cautioned in regard to the possible introduction of tsetse flies into this country similar to the way in which *Anopheles gambiae* was brought into South America. Safety beyond this point seems to rest in the less likely possibility that large animal reservoirs might be developed here.

Diagnosis—Recognition of sleeping sickness depends largely on the presence of an undiagnosed febrile condition characterized particularly by remittent fever with rapid pulse, neurologic symptoms of varying degree and manifestations ranging from tremors and hyperesthesia to marked psychotic states and somnolence. One of the outstanding characteristics is soft, elastic enlargement of the posterior cervical glands.

When the question of diagnosis arises, trypanosomes may be recovered from the enlarged glands and may be found in thick blood films or spinal fluid.

Treatment—Tryparsamide and Bayer 205 are the drugs of

choice in Gambian or West African forms of the disease while Bayer 205 (Naphuride, Winthrop) is used in the Eastern or Rhodesian type.

American Trypanosomiasis (Chagas' Disease)

The title "American" applied to this disease at present means South and Central American. The transmitting agent is the cone-nosed kissing bug *Panstrongylus megistus* (*Triatoma megista*). This bug is present in California and the southwestern United States. It lives in rodent burrows, particularly those of armadillos and opossums, and enters human habitations where it bites its human victims. The bite of the bug is relatively painless and may not awaken the sleeper. Scratching of the bite inoculates the skin with trypanosome-bearing feces that is habitually deposited by the bug in the act of biting.

The animal reservoirs of the disease are armadillos, opossums and other wild rodents. These animals as well as the reduviid bugs have been found infected with trypanosomes under natural conditions in the areas mentioned above.

Chagas' disease is a serious disease of high mortality among children. The trypanosomes produce fever, facial edema and adenitis in the acute stage and cardiac, thyroid, or central nervous system derangements later.

It is obvious that in the United States the disease would be likely to occur only in those areas where the *Triatoma* exists, inhabits rodent burrows where animal reservoirs have been established and where the living and sleeping habits of the people are such as to permit so large an insect as this to gain access to them while sleeping at night. At present these possibilities appear to exist only in areas where the inhabitants live in adobe huts under low economic conditions. Prevention is obvious.

There is no known effective treatment or specific preventive for Chagas' disease.

Visceral Leishmaniasis or Kala-azar

Leishmania donovani is known to exist at present in the Mediterranean area, through India and China, and in South America in Eastern Brazil, the Matto Grosso region of the Paraguay-Brazilian border and in Bolivia. The most likely transmitting agent is the sandfly (*Phlebotomus*) although there is

evidence that it may be transmitted by contact or by contaminated food

Kala-azar is pathologically a blocking of the reticulo-endothelial system. Its important manifestations of marked splenomegaly, anemia and leukopenia with monocytosis are evidences of this disturbance.

An important characteristic of the distribution of visceral leishmaniasis is its marked tendency to limitation to geographic areas by some still unknown factors. Possibly the conditions for propagation by the sandfly are important in this consideration.

No sandfly vector has been identified in the United States and there exists no reason to believe that visceral leishmaniasis will become a disease of this country.

Cases of kala-azar may be seen later in this country in troops returning from infected regions of Asia, Europe and South America. As such they might constitute a serious problem in diagnosis requiring differentiation from other chronic diseases characterized by splenomegaly and anemia. Definite diagnosis can only be made by finding leishmania in smears from spleen or bone marrow puncture.

Cutaneous Leishmaniasis or Oriental Sore

Most that has been said about kala-azar applies to oriental sore insofar as etiology, transmission and distribution are concerned. The specific leishmania is *Leishmania tropica*. Although it exists in most countries where *L. donovani* is present (except South America) there is a tendency for the two organisms to remain discrete in localized areas.

Should it become more firmly established that oriental sore can be spread through direct contact, secondary cases might occur for a while wherever patients with undiagnosed ulcers are permitted to move freely in the population. This would seem to be reason enough for physicians generally to suspect and look for leishmania in recalcitrant ulcers of unknown etiology in returned troops.

American Mucocutaneous Leishmaniasis (Espundia)

The American form of leishmania responsible for this ulcerating condition about the nose and mouth is *L. braziliense*. Like

the other leishmanias it is believed to be carried by the sandfly or spread by contact. The disease is widespread through northern South America and occurs in Central America as far north as Mexico.

A cautious watch should be kept on all undiagnosed ulcerative lesions (goundou) around the nose and mouth of persons returning from endemic regions. Leishmania should be sought for in smears from these sores.

Schistosomiasis

The schistosome flukes producing disease in man are of three species and distributed as follows:

Schistosoma mansoni—North Africa, northern countries of South America and many islands of the West Indies.

Schistosoma haematobium—the African-Mediterranean area, Abyssinia, East, West and South Africa, the countries of the Middle East and the islands of Madagascar, Mauritius and Reunion.

Schistosoma japonica—predominantly found in the valley of the Yangtze in China, the Mekong River Valley of South China and Indo-China and in Japan, Formosa and the Philippine Islands.

All of the schistosomes have a life cycle involving specific forms of snails, and the propagation of the disease in any region is conditioned by the presence of the specific invertebrate host, conditions of the environment favorable to the persistence of the developmental forms of the schistosome both while in the snail and in its free-living state in water sources, and the social habits and customs of the people that bring them into contact with infective forms in these water sources.

No evidence exists that such conditions are present in the United States, and the establishment of any form of schistosomiasis as an endemic disease of this country is hardly to be considered. On the other hand, imported case of schistosomiasis may reasonably be seen here.

Diagnosis—*Schistosoma mansoni* infection must be differentiated from many chronic conditions characterized by ulcers and fistulas about the colon and rectum, bloody stools, ascites and hepatic cirrhosis. *Schistosoma haematobium* is to be suspected in patients coming from endemic areas who present

symptoms referable to the genito-urinary tract particularly hematuria, bladder ulcers and papillomas, and late cirrhotic changes in the liver *Schistosoma japonica* may produce vague intestinal manifestations but will more likely be encountered in the stages of liver cirrhosis and splenic enlargement

When suspicions are aroused in any undiagnosed case which presents symptoms such as the above and the patient has been in an endemic area of the disease, the presence of the characteristic eggs of each species must be looked for

In *S. haematobium* infection the terminal-spined eggs are to be found in the urine or feces, or both, in *S. mansoni*, lateral-spined eggs appear in the feces and rarely in the urine, while the spineless eggs of *S. japonica* occur only in feces

Yaws (Frambesia)

This is a chronic infectious spirochetal disease caused by *Treponema pertenuis*. It is transmitted by direct contact in most instances but may be mechanically carried from person to person by common flies. It is nonvenereal.

The disease is well established in the West Indies and the coastal area of Colombia but in spite of its ease of spread has never been present in continental United States. It is a common disease of Africa, Southeast Asia, the Philippines and the Polynesian Islands.

Yaws develops as an initial lesion on some exposed part of the body as a granulating papilloma known as the mother yaw, and in the course of a few weeks appears on other parts of the body as daughter yaws. A yaw cleaned of its superficial crust presents small elevated proud-flesh-like granules with yellowish white tips giving it the appearance of a raspberry from which the name of the disease, "frambesia," is derived.

Extensive involvement of the mucous membranes and subsequently the submucous tissues and bones of the nose, mouth and palate may occur, giving rise to the disfiguring destructive ulcerations and necrosis of these parts known as *gangosa*. Similar destruction of soft tissues in the anal region results in anal strictures.

Diagnosis of yaws is made by dark-field examination of the tissues and the finding of the specific spirochete. The Wassermann test usually becomes positive sooner or later.

Mild *antisyphilitic treatment* by means of the arsenicals usually results in rapid and complete cure of the disease

CONCLUSION

The tropical diseases considered here are all of immediate concern to every physician in this country. Those conditions already with us must be recognized, controlled and eliminated by the concerted action of our entire medical profession. Tropical diseases once existing here can recur if we permit our standards to revert in any community to those under which they formerly thrived. The exotic diseases beyond our continental boundaries may become of immediate concern to any physician called upon to diagnose and treat their unfamiliar manifestations in service men or civilians returning to their home communities from foreign travel.

The young doctors among us may find themselves facing the problems of many diseases of foreign lands within a matter of months, weeks or even days.

On our profession as a whole and on the official agencies particularly, falls the immediate necessity to be aware, to overestimate rather than underestimate our potential dangers and to exert every effort to maintain our high health standards in this country.

Every physician should be informed by literature and any other practical means of the tropical diseases of concern to the home front, he must at least know to whom to turn for help when he needs it.

THE MENINGITIDES AND ENCEPHALITIDES

ALISON H PRICE M D *

THE MENINGITIDES

PURULENT meningitis has always been a medical emergency and with the exception of meningococcus meningitis, the prognosis has been extremely poor. The case mortality rate for those who developed acute purulent meningitis was over 90 per cent. The use of sulfonamide compounds has lowered the mortality rate appreciably, but has not detracted from the emergency which exists when a case of purulent meningitis is encountered.

Diagnosis depends on the following clinical observations and laboratory findings: (1) sudden onset, (2) headache, (3) malaise, (4) fever, (5) nausea and vomiting, (6) stiff neck, (7) positive neurological signs, (8) increased intraspinal pressure, (9) changes in the cerebrospinal fluid and (10) demonstration of the causative micro-organism.

Arranged in the order of frequency the more common bacteria causing acute purulent meningitis are: (1) meningococcus, (2) *Streptococcus hemolyticus*, (3) pneumococcus, (4) influenza bacillus and (5) staphylococcus.

The meningococcic infection is found most frequently in the epidemic form and when one of the other organisms is the cause, the meningitis is usually sporadic or secondary to pneumonia, empyema, abscess, peritonitis, otitis media, pericarditis, sinus infection, injury or operation.

MENINGOCOCCIC MENINGITIS

Meningococcic meningitis (cerebrospinal fever, epidemic meningitis) occurs in sporadic and epidemic forms. The epidemics are irregular in appearance and are apt to be more severe during war. They involve both military and civilian populations. There were thousands of cases of meningococcic meningitis during the World War I and during the present war there have

* Ross V Patterson Fellow in Medicine, Jefferson Medical College and Hospital

been large epidemics in England. In this country the increase in the number of sporadic cases has reached epidemic proportions, however, the incidence rate of the disease at the peak has been below the peak rate of 1917-1918.

CLINICAL PICTURE—*Headache* is the most common and earliest symptom of meningitis regardless of cause. The headache of meningitis is often intense and agonizing. The onset is usually sudden with *malaise*, high or gradually rising *fever*, and *stiffness of the neck*, slight at first, increasing as the disease progresses and often causing retraction of the head. Other signs common in meningitis are dizziness, convulsions, restlessness, insomnia, vomiting, drowsiness, stupor, petechiae or purpura and finally coma and delirium.

The *petechiae* or purpura are noticed more frequently during epidemics and are most marked in the fulminating septicemic forms when there may be large hemorrhagic areas scattered over the body. Meningococci have been cultured or seen in direct smears from these purpuric lesions of the skin.

The positive *signs* usually found are Kernig's, Brudzinski's and contralateral Brudzinski's, and in a variable number of cases Babinski's sign. The pulse is slow (bradycardia) in proportion to the temperature elevation. The leukocyte count of the blood is elevated early and is from 15,000 to 35,000 per cu mm.

DIAGNOSIS—In all patients the *cerebrospinal fluid* should be examined. The cerebrospinal fluid is removed aseptically by inserting a needle in the area between the third and fourth lumbar vertebrae. If local anesthesia is used, infiltration of the skin is all that is necessary. Care must be taken not to inject any of the anesthetic agent into the spinal canal. Cocaine hydrochloride and nupercaine are preferable to procaine hydrochloride as the latter inhibits the action of the sulfonamide compounds. Whenever possible the initial spinal fluid pressure should be measured. The spinal fluid pressure, if increased, should be slowly reduced, drop by drop, to approximately a normal figure. For examination, 5 to 10 cc of spinal fluid is collected in each of two sterile test tubes with rubber or cork stoppers. The collected fluid is smeared on a glass slide and stained with Gram's stain. To stain with methylene blue is only adding another step. A differential cell count of the stained smear should be done to classify the types of leukocytes and to find intracellular or extracellular

bacteria The presence of stained bacteria on the slides is not sufficient, however, for a final etiologic diagnosis, which can be based only on fermentation reactions and serologic identification The total cell count should be made very soon after the spinal fluid is collected, as cells soon stick together and to the sides of the tube, making later counts inaccurate If a clot forms, an accurate cell count is impossible

Blood agar heated to form chocolate agar is especially convenient for direct *culture of the spinal fluid* at the time of the lumbar puncture. It supports the growth of all the organisms commonly causing meningitis The media should be warm and should be streaked immediately on a plate, placed in an incubator or transported to the laboratory in a heated box Cox, McDermott and Mueller have shown, however, that meningococcal material for culture can be preserved for two or three days over a considerable temperature range by immersing the swab in a few drops of sterile horse blood, thus making possible shipment of specimens through the mail and materially simplifying the manner of examination of carriers in the field

Blood culture should also be made early The blood should be obtained by aseptic venous puncture at the bedside Approximately 10 cc of blood is injected into a flask containing 100 cc. of effusion broth Growth of meningococci is shown by clouding of the broth media or partial hemolysis of the blood and occurs in from twenty to seventy-two hours When the patient has received one of the sulfonamide compounds prior to study, it is necessary to add para-aminobenzoic acid, 5 mg per 100 cc of culture media This prevents the sulfonamide compound from acting on the organism being cultured When there is any growth the organism should be preserved for future reference.

TRANSMISSION—Transmission is from man to man It is often difficult to trace direct contact between cases of meningococcic meningitis The difficulty is probably the result of the relative immunity to the meningococcus of a large percentage of the population If they have harbored the organism at one time or another and developed some immunity, they may be healthy carriers of a virulent strain and may pass this organism through a long chain of individuals before it reaches one in which the conditions for invasion are ideal When this patient becomes ill, it is often impossible to trace the intervening chain of passage.

PROPHYLAXIS—The patient with meningococcic meningitis should be isolated. The problem of treating carriers is unsettled. However, Mueller took approximately 400 individuals and gave one-half of these sulfadiazine for three successive days 3 gm. on the first day and 2 gm. on each of the following days, and the other half of this group of 400 served as controls. Three days after the administration of the drug, nasopharyngeal cultures of all 400 individuals were taken. In the control group type I carriers had increased from 68 to more than 70 per cent, but of the 200 who had received sulfadiazine not a single one carried meningococci. Based on these findings it might be advisable in epidemics of meningococcic meningitis to treat contacts with doses of sulfadiazine, and in an emergency it may be possible to eradicate carriers in a given group of individuals.

TREATMENT—*Lumbar puncture* is done when the patient is first seen, both as a diagnostic measure and as treatment to relieve increased intraspinal pressure. The reduction of pressure will in many cases alleviate the patient's headache and restlessness and make the nursing care much easier. The lumbar puncture is repeated six hours following admission if the patient is still restless and uncooperative and complaining of agonizing headaches, otherwise, it is not repeated unless the patient fails to respond to treatment or there are signs and symptoms of a relapse. If delirium, restlessness and headaches are not relieved by repeated lumbar punctures, paraldehyde, barbiturates, codeine sulfate, and even morphine sulfate have been advised.

The introduction of the sulfonamide compounds in the treatment of meningococcic meningitis has not detracted from the great importance of *good nursing care* which every patient needs. If the patient has urinary retention, catheterization may be necessary. Care must be taken by the nursing staff to prevent the development of bed sores and the mouth and eyes need constant attention. The patient must be given a nourishing diet and if his urinary output falls below 1000 to 1500 cc., fluid intake must be increased either orally or intravenously. A solution of physiological sodium chloride is satisfactory for intravenous use, however, if it is necessary to give more than 2000 cc. of fluid to equalize the water balance, alternate injections of 5 or 10 per cent glucose in distilled water are advocated.

Chemotherapy—In the treatment of meningococcic menin-

gits the sulfonamide compounds are highly efficacious Sulfanilamide, sulfapyridine, sulfathiazole and sulfadiazine have all been used with success, but sulfadiazine is the least toxic and is the drug of choice. If sulfapyridine, sulfathiazole or sulfadiazine is to be given intravenously, the sodium salt may be used. A 5 per cent solution of the sodium salt is recommended. These salts are highly alkaline and care must be taken that the solution does not escape into the tissues.

SULFANILAMIDE

SULFAPYRIDINE

SULFATHIAZOLE

SULFADIAZINE

Fig. 145—Sulfonamide crystals in the urine

The initial oral dose is 4 gm. (60 grains) and subsequent doses of 1 gm. (15 grains) are given every four hours day and night until the temperature remains normal for five days. It is satisfactory and it has been our practice to give the initial dose intravenously as in this manner a high blood level is obtained more rapidly than is possible with administration by mouth. Furthermore, this method is applicable to those patients who

have nausea and vomiting in whom it is impossible to give the drug by mouth. An injection is made of 5 or 6 gm of sodium sulfadiazine in 100 cc of distilled water. This is followed in six hours by an additional 3 gm of the sodium salt intravenously and starting at that time 1 gm of sulfadiazine every four hours by mouth. This averages approximately 6 gm per day for adults. For infants and children 0.1 gm per kilogram of body weight per day is given. A blood level of approximately 10 mg per 100 cc should be maintained with the sulfonamide compounds. The urine should be examined daily for the presence of sulfonamide crystals (Fig 145). The determination of the drug level in the cerebrospinal fluid is not important. As mentioned, 1 gm of the sulfonamide drug every four hours is continued orally for five days after recovery has occurred and the temperature has returned to normal.

The sulfonamide drugs should not be given intrathecally. They may be given subcutaneously as recommended by Taplin and his associates, using a concentration of approximately 0.3 to 0.7 per cent solution, that is, from 3 to 7 gm of the sodium salt in each liter of a physiological solution of sodium chloride. These concentrations of the sodium salts may be given without fear of causing local necrosis or slough.

Serum—If the patient fails to show improvement following forty-eight hours of adequate chemotherapy with one of the sulfonamide compounds, then antiserum may be used which contains antibodies for the type of meningococcus present. At the present time only two groups of meningococci need be considered, namely, group I which includes types I and III and group II which includes all the remaining types. The meningococci may be identified in a manner similar to the Neufeld reaction used in typing pneumococci, or if this method is not satisfactory the serological identification of the meningococcus may be accomplished by agglutination tests. If the specific antiserum is not available, the polyvalent serum may be used.

If one is prudent the following directions must be followed when giving serum:

- 1 The patient or family should be questioned for possible sensitization, such as history of asthma, angioneurotic edema, hay fever, sensitivity to horse dander, rabbit hair or injections of serum more than seven days previously.

2 Before injecting any serum, tests to determine sensitization are in order

3 A hypodermic stimulant must be at hand (epinephrine hydrochloride 1 1,000)

4 The serum should be at hand or room temperature *Do not heat*

5 Injection should be slow

The amount of serum necessary to give an excess of antibodies may vary from 20 cc to as much as 100 cc There is no convincing evidence that the intrathecal administration of serum is of any value and as it may be harmful it is not recommended There is no substantial evidence to support the use of antitoxin

COMPLICATIONS—Sequelae and complications are deafness, ocular palsy, strabismus, optic neuritis and changes in mentality The complications which occur or result whenever serum is given with therapy or which may be common with chemotherapy may also be seen when the patient is being treated with either or both of these agents If a relapse or recurrence takes place the patient should be treated as though he or she were a new patient and serum used if indicated

STREPTOCOCCUS HEMOLYTICUS MENINGITIS

Streptococcus hemolyticus meningitis is seen most frequently with mastoiditis and otitis media

DIAGNOSIS—Diagnosis is dependent upon the signs and symptoms of meningitis plus a history of positive physical findings of foci of infection particularly involving the ear, mastoid process, paranasal sinuses, nose, jaw or teeth, and the presence of hemolytic streptococci in the spinal fluid

PROPHYLAXIS.—The routine use of sulfonamide compounds in patients with acute otitis media and mastoiditis seems of value It is advisable to start chemoprophylaxis at least twenty-four hours prior to operation for mastoiditis and to continue this drug for one to two days after the operation The same procedure may also be used in operations for brain abscess.

TREATMENT—The mortality rate has been greatly reduced by the use of the sulfonamide compounds Sulfadiazine is the drug of choice, then in turn come sulfapyridine and sulfanilamide As in treating all patients with meningitis, a high blood level seems to be of some advantage and should be approxi-

mately 10 mg per 100 cc The drug should be continued for eight days after the spinal fluid becomes sterile and all other evidence of infection has subsided (for dosage and methods of administration see Meningococcic Meningitis). During treatment the blood count should be checked frequently, the level of the sulfanilamide compound should be determined daily and the urine examined for red cells and crystals of the particular sulfanilamide compound being used (Fig 145) If anemia becomes marked, due either to the treatment or to the hemolytic streptococcus infection, small blood transfusions (200 to 300 cc) should be repeated daily or on alternate days as indicated by the erythrocyte count Care should be taken to see that the blood is typed and cross-typed before each transfusion The value of specific serum and of immunotransfusion is still in doubt If in the future the streptococci are grouped and typed and specific serum for each type is available, it may be of some value as an adjuvant to sulfonamide therapy.

Penicillin (filtrate of broth culture of *Penicillium notatum*) is effective in hemolytic streptococcus infections and has the advantages of being relatively nontoxic, highly soluble, nonhemolytic and is active in the presence of pus and para-aminobenzoic acid Unfortunately, bacteria may become penicillin-fast The value and limitations of penicillin are not yet determined, however, it appears promising

PNEUMOCOCCIC MENINGITIS

Pneumococcic meningitis is rarely primary, but occurs after injury of the head, pneumonia or other infections of the respiratory tract and may be a complication following septicemia, otitis media, mastoiditis and sinusitis Pneumococcic meningitis following pneumonia has an extremely poor outlook and if endocarditis develops with evidence of a bacteremia, the disease is fatal in almost every case Although it has been said by some that the mortality rate since the advent of sulfanilamide compounds has been about 35 per cent, unfortunately it has been our experience that this is entirely too low and that the mortality rate in cases of pneumococcic meningitis is nearer 85 per cent

DIAGNOSIS—Diagnosis is dependent upon the signs and symptoms of meningitis plus a history of pneumonia, septicemia, otitis media, mastoiditis or sinusitis and the presence of the pneumococcus in the spinal fluid

PROPHYLAXIS—The prevention of exposure, the prompt treatment of lobar pneumonia and the routine use of sulfonamide compounds in patients with otitis media and mastoiditis comprise the prophylactic measures

TREATMENT—Sulfadiazine is the drug of choice and high blood levels (10 mg per 100 cc) should be maintained (See Chemotherapy under Meningococcic Meningitis) The drug is continued for fourteen days after the cerebrospinal fluid becomes sterile and after all evidence of infection has completely subsided When the pneumococcus is isolated it should be typed and type-specific antipneumococcic serum may increase the chance for recovery As therapeutic rabbit serum is now available for almost all the types of pneumococci encountered, type-specific antiserum should be given intravenously, 200,000 units as the initial dose (see precautions under Treatment of Meningococcic Meningitis, page 1502) The antiserum should be given slowly in one injection over a period of five or ten minutes Additional doses of 100,000 units should be given every twelve hours until a positive balance of antibodies is obtained and maintained I do not believe that intrathecal administration of serum is of any proved worth In numerous cases relapses occur after patients are apparently cured, and in the majority of these they fail to respond to any further treatment

INFLUENZA BACILLUS MENINGITIS

(*Hemophilus Influenzae*)

Influenza bacillus meningitis is seen most frequently in children and infants Almost all affected children under the age of two years die Treatment in older patients seems to result in a lower mortality rate The organism may be found in the bloodstream early in the disease When seen in the spinal fluid, it is a tiny, pleomorphic gram-negative bacillus which can be seen on direct smear The type of influenza bacillus can be determined by the capsular swelling when the specimen is treated with specific rabbit antiserum, or by precipitation with the use of clear supernatant spinal fluid There are six known types of influenza bacillus, which are immunologically distinct, and they are classified as types a to f Of these, type b produces a great majority of infections in children

The value of sulfonamide compounds in the treatment of

influenza bacillus meningitis is not proved. Those patients reported as having recovered are for the most part in the older age group in which occasional spontaneous recovery occurs. Recently, rabbit antiserum specific for type b influenza bacillus has been used with encouraging results. If the organism is type b, intravenous serum therapy should be employed in the early stages. If the organism is not type b or cannot be typed, then one of the sulfanilamide compounds, preferably sulfathiazole, should be used in doses as outlined under Treatment of Meningococcic Meningitis.

It is suggested by some that if the patient fails to respond to the intravenous administration of serum, the intrathecal administration of antiserum and complement should be considered, however, I do not believe that the present value of this procedure justifies its use.

STAPHYLOCOCCIC MENINGITIS

Staphylococcic meningitis is usually preceded by a history of an abscess or other foci of infection. Sulfathiazole appears to be the drug of choice, however, the treatment of this disease is not satisfactory at the present time. It has been suggested that because there is tendency for the staphylococcic infection to recur or to become chronic, therapy with the sulfonamide compounds should be continued from two to four weeks after the infection has cleared. Dosage and routes of administration for the sulfanilamide compounds were given previously under Meningococcic Meningitis.

It has been advocated by Julianelle that staphylococcus antiserum may be used in cases resistant to the drug or as a supplement to sulfonamide therapy. The average total dose ranges between 80 and 200 cc of serum. It has been suggested that 60 cc be given on the first day, 40 cc on the second day and 20 to 40 cc on subsequent days. The antitoxin is not of proved worth.

Penicillin may eventually prove to be most useful.

THE ENCEPHALITIDES

A list of the known forms of primary encephalitis, particularly those caused by filtrable viruses, is as follows: St. Louis encephalitis, Japanese encephalitis, Russian encephalitis, eastern equine encephalitis, western equine encephalomyelitis, lympho-

cytic choriomeningitis, poliomyelitis, lethargic encephalitis, (Von Economo or Vienna type), rabies, West Nile Fever, lymphogranuloma venereum and herpes simplex. One may gain the impression from this classification that the matter of etiologic diagnosis of encephalitis is an easy one and that most cases fit into one or another entity. In a great majority of sporadic cases, however, an etiologic diagnosis cannot be made with the knowledge and technic now available. The response of the central nervous system to the neurotrophic virus is of such a uniform nature that the clinical and pathological features of most of the virus encephalitides are so similar that it is usually impossible or difficult to make an etiologic diagnosis without laboratory help. With numerous outbreaks of encephalitis, the following may be helpful for classification: (1) distribution of cases according to age, sex and occupation, (2) seasonal incidence, (3) neurological residuals or cranial nerve palsy, (4) spinal fluid examination for number and type of cells, and (5) mortality rate. The course of the patient's illness, regardless of the etiologic agent, may vary from headache, malaise and slight fever lasting a day or two to the extreme case in which death may occur twenty-four to forty-eight hours after onset.

ENCEPHALITIS LETHARGICA

(Epidemic Encephalitis Von Economo's Type of Encephalitis)

The etiologic basis of this disease is not known, but is believed to be a virus. While this illness may occur in any season, it is the only one of the encephalitides which has occurred as an epidemic during the winter months. No age is exempt, although the incidence appears to be greater in the age group of ten to forty-five years.

CLINICAL PICTURE—The onset may be sudden or gradual and the symptomatology depends upon the parts of the brain involved. The patient may not be sufficiently ill to be bedfast or the infection may be overwhelming and the patient die after a brief illness. The symptoms are chiefly headache, lethargy, malaise, stiffness of the back and diffuse pain. Fever is usually present and it may be brief or last for weeks. High fever has a bad prognostic import. Approximately three-quarters of the cases show lethargy. In these the patients are easily aroused and seem to be rational for time and place. Almost one-half of the

cases show eye symptoms Among these are strabismus, photophobia, nystagmus, ptosis and blurred vision

DIAGNOSIS—Diagnosis is frequently arrived at from the symptoms and signs of encephalitis with normal spinal fluid protein and sugar The cell count of the spinal fluid may be slightly elevated or normal and the pressure at times is elevated The differential diagnosis of an intracranial lesion is definitely ruled out by the physical findings and the lack of changes in the optic fundi Diagnosis is based upon (1) lethargy, (2) eye symptoms, (3) prolonged course, (4) chronic manifestations, particularly parkinsonism, (5) negative serological test with a known virus infection, and (6) negative Wassermann reaction The patient may make an uneventful recovery or he may progress into the chronic form and develop ocular motor palsy and other neurological residuals, among which are parkinsonism, tremor, rigidity and oculogyric crises

TREATMENT—Treatment for these patients is symptomatic The patient should be kept warm, the fluid intake should be 3000 or 4000 cc for twenty-four hours and the diet should be liquid or soft In the acute cases the patients should be isolated, since there is some question as whether or not the disease is spread by contact Repeated lumbar punctures and the intravenous use of hypertonic salt solution or a 50 per cent glucose solution helps to relieve headache and to diminish the drowsiness in the early stages when the spinal fluid pressure is increased Nocturnal restlessness may be treated with chloral, barbitol, or phenobarbital Hypersomnolence, if marked, must be treated by nutritional maintenance with the stomach tube, by intravenous therapy, or by hypodermoclysis If convulsions are persistent it may be necessary to use intravenously one of the barbiturates, either sodium amytal, 0.2 to 0.5 gm (3 to 7½ grains), or sodium luminal, 0.9 gm (1½ grains) If paralysis occurs with bladder and bowel incontinency, great care must be taken with the patient An indwelling catheter with tidal drainage is indicated, he should be kept dry and all possible precautions should be taken to prevent bed sores He should occasionally be rolled from side to side in bed

Treatment of the *neurological residuals* is as follows For the postencephalitic parkinsonism, atropine sulfate in an 0.5 per cent solution is given by mouth. Adults receive 1 drop in water

three times a day as the initial dose, and the dosage is not increased too rapidly. At the end of five days this may be increased to 2 drops three times a day and another tolerance period maintained. This gradual increase in dosage is continued until the optimal point is reached, this may be from 6 to 15 or 20 drops three times a day. If the patient develops blurring of the vision, flushing, diarrhea, palpitation or retention of urine the drug must be stopped for a few days and started again at a lower dosage. If the patient is unable to tolerate the atropine or belladonna, syntropan, a synthetic drug with the characteristics of atropine, may be used. This is first given in a dosage of one 200-mg tablet three times a day, the dosage later being gradually increased. It may be continued for a long period of time, but is not quite as satisfactory as atropine. For tremor, stramonium may be given as tincture of stramonium, 1 cc or 15 drops three times a day, the dosage being gradually increased until 50 to 75 drops a day are being given in three doses. Benzodrine sulfate has been suggested in doses of 10 mg once to four times daily. It is of little value, however, since the small doses are ineffectual and large doses disturb the patient's sleep. In young subjects and older patients who are good operative risks and in whom the persistent tremor is not controlled by drugs, operative treatment must be considered. One of these operations is the removal of the opposite premotor cortex. This leaves no residual paralysis, but results in a loss of the tremor.

ST LOUIS ENCEPHALITIS

(Epidemic Summer Type of Encephalitis)

The St. Louis type of encephalitis is a virus disease which involves the central nervous system and the meninges. The symptoms depend upon the extent of the involvement. This disease may occur either epidemically or sporadically. The malady is endemic in America, and epidemics occur in the late summer. The *morbidity and mortality rates* increase progressively with each decade of life. No age is exempt. The highest incidence is in individuals more than twenty-five years of age. The *incubation period* has been estimated to range from four to twenty-one days.

CLINICAL PICTURE.—As in the other encephalitides, the cases vary from mild or abortive cases, which exhibit only headache

and fever, to those with an abrupt onset, characterized by high fever, nausea, vomiting, vertigo, headache, nuchal rigidity, Kernig's sign, mental confusion and tremor. Paralysis is not a common finding in these cases and involvement of the ocular muscles is extremely rare. Spinal fluid is usually under increased pressure, but is free from any ordinary bacteria, either by smear or culture, the sugar is not diminished and may be increased or normal, globulin is increased and the total cell count is increased, the increase usually consisting chiefly of lymphocytes. Those who recover from this disease usually do so quickly, the temperature falling by lysis and reaching a normal level in five to ten days. In exceptional cases it may persist for three to six weeks. Those who recover are not usually bothered by troublesome or disastrous sequelae.

DIAGNOSIS—Diagnosis depends upon the isolation of the virus from brain tissue (as blood, spinal fluid and nasal washings are not infective), or by showing the development of neutralizing and complement fixing antibodies during convalescence. It has been shown where epidemics have been prevalent that 50 per cent or more of the normal population may have antibodies to St. Louis encephalitis virus. A single convalescent specimen is of no value in making a positive diagnosis, although it is of considerable significance if it is negative. For this reason it is necessary to have a specimen of serum taken when the patient is first ill, two weeks thereafter and at six weeks. In this way an increase in the titer of the neutralizing antibodies or the complement can be demonstrated showing the recent infection by the virus in question.

Transmission of this disease is by mosquito vector. Droplet infection transmission from man to man has never been proved. The *natural reservoir* for this disease is mammals and birds and possibly human carriers.

TREATMENT—The treatment, as outlined previously for Encephalitis Lethargica, is symptomatic as there is no specific vaccine, drug or serum which is of value. The spinal fluid pressure should be kept within the limits of normal by repeated lumbar punctures, and the intravenous injection of hypertonic glucose solution may relieve the headache. Fluid intake should be freely maintained and if necessary the patient should be fed by gastric tube.

PROPHYLAXIS—There is no efficient vaccine available at the present time

EASTERN EQUINE ENCEPHALITIS

Eastern equine encephalitis is an epidemic disease of the late summer. The majority of reported cases have occurred in children under ten years of age. The *mortality rate* in recognized cases has been approximately 60 per cent.

CLINICAL PICTURE—The onset of the disease is usually sudden, particularly in the younger children, with the temperature rising rapidly to 103° to 105° F. Convulsions occur during the course of the disease. Coma may develop rapidly and persist throughout the acute stage of the illness. There is nuchal rigidity, positive Kernig's sign, stiffness of the back, and sometimes in the younger patients a peculiar edema of the face and upper extremities. Eye signs have been common and ocular motor palsies are present. Early in the illness there is a leukocytosis. The spinal fluid is under increased pressure and its total cell count is increased, averaging approximately 2000 per cubic millimeter. Early in the illness the majority of these cells are polymorphonuclear leukocytes, however, later in the illness there is a predominance of lymphocytes. In the patients who recover the temperature returns to normal by lysis, usually six to ten days after the onset.

In the reported cases eastern equine encephalitis differs from western equine encephalomyelitis and St. Louis encephalitis in that a large percentage of those who survive it have severe mental or physical damage.

DIAGNOSIS—Diagnosis in man depends upon the development of specific neutralizing and complement fixing antibodies or the isolation of the virus from the brain. It is believed that the blood and spinal fluid are infective before the onset of the neurological signs and symptoms. The *natural reservoir* for this disease is birds and mammals and the vector is most probably a mosquito.

PROPHYLAXIS—As this disease may reach epidemic proportions and the vector is the mosquito, mosquito control must be considered. In horses, formalized chick embryo vaccines have been successfully used.

TREATMENT—There is no specific therapy and the treatment is entirely symptomatic. (See Treatment under Encephalitis Lethargica.)

WESTERN EQUINE ENCEPHALOMYELITIS

Western equine encephalomyelitis is epidemic in the late summer. This disease is usually a milder variety of the same clinical picture as eastern equine encephalitis, but it has occurred mainly in adults, a large proportion of whom have been male agricultural workers. The *mortality rate* for this age group is approximately 5 per cent. In infancy and in old age the mortality rate is higher.

CLINICAL PICTURE—Clinically, the diseases caused by St. Louis virus and western equine encephalomyelitis virus are so similar that it is impossible to differentiate them clinically. *In infants* the infection is usually of a sudden onset, with fever, refusal to eat followed by vomiting, rigidity of the neck, twitching and occasionally convulsions. The temperature rises to 103° to 105° F and remains at that high level for twenty-four to forty-eight hours. In most cases the temperature falls to normal in the next three or four days. Cyanosis may be conspicuous during the acute illness. The child may completely recover in from four or five days to a week after the onset of the illness. It is extremely important in treating these children that repeated lumbar punctures be done to keep the spinal fluid pressure at approximately normal level. This greatly reduces the number of cases with permanent residual damage.

In adults the disease is very similar to eastern equine encephalitis. The clinical picture, however, is usually milder and recovery usually takes place within two or three weeks. The spinal fluid is usually under increased pressure with cell count varying between 15 and 500 cells. During the first days of the illness there may be an increase of polymorphonuclear cells up to or more than 50 per cent, but later the lymphocytes predominate. Here also it is believed that the spinal fluid and blood are infected before the onset of neurological symptoms and signs, but in order to make a diagnosis it is necessary to isolate the virus from the brain or to demonstrate the development of neutralizing or complement fixing antibodies in the convalescent serum. The *natural reservoir* is thought to be birds and mammals and the vector is probably the mosquito.

PROPHYLAXIS—Formalized chick embryo vaccine has been used, and anyone who by reason of his work must be heavily exposed to mosquito bites in an endemic area should be offered

the probable protection afforded by this vaccine. There seems to be no reason for hesitating to vaccinate those who request it. It is recommended that 1 cc be given subcutaneously in each of two doses at weekly intervals, and that the patient be observed for one hour after vaccination, adrenalin being kept immediately available to combat any anaphylactic type of reaction.

Mosquito control for the community should also be stressed. Because of the number of known viruses that are transmitted by the mosquito and the great likelihood of the existence of others which so far have not been isolated, it might be reasonable to emphasize mosquito control as a general prophylactic measure and one especially appropriate in this disease, where the morbidity rate is so low.

JAPANESE ENCEPHALITIS

In Japan there have been two varieties, type A and type B. Type A seems to be the same as Von Economo's encephalitis. Type B resembles very closely St. Louis encephalitis, but there are some serologic differences between their viruses. The average *mortality rate* is approximately 65 per cent. Spinal fluid cell increase is chiefly in lymphocytes. Neurological residuals are infrequent. *Diagnosis* in men is dependent upon isolation of the virus from the blood, rarely is it ever found in the spinal fluid or the brain. The development of neutralizing and complement fixing antibodies in the sera of convalescent patients is of diagnostic aid. *Transmission* is believed to be by the mosquito vector, probably the *Culex*. There is no conclusive proof that the disease can be transmitted by droplet infection from man to man. *The natural reservoir* is believed to be horses and, questionably, human beings. Clinically this encephalitis is indistinct from St. Louis encephalitis.

PROPHYLAXIS.—There is no efficient vaccine available at the present time and mosquito control must be considered.

RUSSIAN ENCEPHALITIS

Russian encephalitis is endemic in the late spring and early summer. It is also called verno-aestival or tick-borne encephalitis, and most frequently affects males, principally forest workers. The *mortality rate* is given at approximately 30 per cent. Spinal fluid pressure is increased and the cell count varies from ap-

proximately 25 to 150 cells, these are chiefly lymphocytes In 20 per cent of the cases there is some residual atrophy, and paralysis of the neck and shoulder girdles is present The disease in man is *transmitted* by ticks and the *natural reservoir* is said to be wild rodents and ticks *Diagnosis* in man depends upon the isolation of the virus from the blood, spinal fluid and brain and the development of neutralizing antibodies

PROPHYLAXIS—Personal prophylaxis against ticks and active immunity with a formalized mouse-brain vaccine have been used *Treatment* of this disease is symptomatic

RABIES

(Lyssa or Hydrophobia)

Rabies is widely distributed in mammals and has been transmitted to man by dogs, cats, cattle, horses, sheep, swine, wolf, fox, skunk, squirrel, raccoon, vampire bat and rat Although rabies is usually passed from some recognized case it may occur from an unknown origin A definite instance of rabies in animals and man in the West Indies and South America has followed the bite of an apparently healthy vampire bat Rabies virus may lurk in unsuspected skunks and foxes in their natural habitat before giving rise to an epizootic Other animal species not yet implicated may also harbor the virus and thus constitute additional unknown sources of infection Despite these possibilities, rabies, as known in this country, rises mainly not from healthy carriers but from animals in some stage of the disease The dog is involved nine times more often than all other animals combined

The rabies virus rarely penetrates the intact body surface Usually there must be a wound and a sufficient amount of virus present before infection can take place The virus passes from the site of the bite along the nerve to the central nervous system Once the virus has gained a foothold in the spinal cord or brain, the animal or patient is doomed The percentage *mortality* from rabies following the bite of a presumably rabid dog ranges from 2 per cent to more than 50 per cent.

DIAGNOSIS—Diagnosis depends upon the demonstration of Negri bodies in certain nerve cells, especially in the pyramidal and ganglion types in Ammon's horn The final and most conclusive test for rabies is the inoculation of mice for the isolation and identification of the virus from Ammon's horn tissues

Webster has developed and described a mouse inoculation test for the diagnosis of rabies

RABIES IN THE DOG—If a dog is suspected of having been exposed to rabies, it should be isolated for a period as long as three months. If it is well after two months it may be released with the knowledge that only rarely does the animal develop rabies after this time. If the animal becomes ill it should be carefully observed until it dies or becomes prostrate. Then it should be killed and the Negri body test should be performed on the brain tissue. If both clinical disease and the Negri bodies are typical, the mouse test may be regarded as superfluous. If the animal does not develop typical rabies, a qualified person must take the responsibility of deciding whether the disease is sufficiently suggestive of rabies to kill the animal. In this case the mouse inoculation test becomes imperative and yields a result which is reliable. If the test is positive, the rabies virus was present in the brain, whether or not the animal appeared sick or had Negri bodies. If the mouse test is negative, the animal did not have rabies. When a questionable dog is killed or found dead, its brain should be examined for Negri bodies and also the mouse inoculation test should be performed. The mouse test should be used in all doubtful cases.

RABIES IN MAN—Once the disease develops in a human the patient is doomed, consequently all treatment must be symptomatic. The patient is to be kept as quiet as possible in a darkened room. Chloroform and morphine may be used for sedation. Occasionally the application of cocaine to the throat will allow the patient to take liquid nourishment. If the patient is unable to swallow readily, fluid should be given parenterally.

PROPHYLAXIS—By the muzzling of dogs the disease can be greatly reduced. Although preventive vaccination of dogs has been done, it has been unsatisfactory. If an individual is bitten by a suspected animal, bleeding should be encouraged and the wound opened and washed with bichloride of mercury 1:1,000 solution. It has been recommended that fuming nitric acid be applied to the bite. If this is done, vaseline should be applied around the wound to avoid burning the surrounding tissues, and the acid applied drop by drop. A pipette or glass rod may be used for this purpose. The worth of fuming nitric acid has not been proved and it seems very likely, as McMaster and Hudack

have shown, that the lymphatics quickly pick and carry away any particles that are introduced into an open wound Therefore, when the face is involved, especially in women, it is questionable whether the acid should be used at all

Vaccine prophylaxis consists of daily injections of rabies vaccine for at least fourteen days The vaccine, usually 2 cc, is injected subcutaneously following sterile precautions, a quadrant of the abdomen is used each day and each injection is separated as far as possible from the previous site During treatment the individual is permitted to lead a normal life but is advised to avoid unusual exercise The dose is the same for persons of all ages, but it is always increased in quantity or number in cases of severe bites Webster recommends vaccine treatment in the following circumstances "(1) Persons bitten through the skin by animals proved rabid, (2) persons bitten through the skin by animals which cannot be proved nonrabid, (3) persons without bite but in intimate contact with rabid dog, moistened by saliva, etc, and (4) persons without bite but in intimate contact with possibly rabid dogs" Many authorities advise against treatment of persons not bitten or scratched through the skin except in the case of children who have had an intimate contact with a dog known to be rabid

WEST NILE FEVER

This virus was isolated from the blood of natives with a febrile illness in Uganda. It is immunologically related to the viruses of St Louis and Japanese encephalitis Little is known of the clinical diseases it produces It seems to be widespread throughout Central Africa

ASCENDING MYELITIS

This or the so-called Landry's type is an ascending paralysis which may be caused by several agents It is the common experience that the etiologic agent cannot be isolated in all of these cases The occasional finding of rabies virus in patients with this disease was mentioned before Furthermore, in young adults poliomyelitis may present a picture corresponding to the Landry's paralysis Acute infectious polyneuritis (infectious neuritis), manifests itself in the Landry's type of paralysis more

often than in other diseases. There is no definite evidence that polyneuritis is a virus disease.

POSTINFECTIOUS HEMORRHAGIC ENCEPHALITIDES

These encephalopathies may occur following measles, mumps, influenza, varicella, or vaccina, after rabies treatment, following arsphenamine therapy, or without any known previous infection. In both types of disease, demyelinating lesions are found on histological section and these are pathognomonic. The distribution of the demyelination varies somewhat in the two encephalopathies, as does the amount of hemorrhage. The etiology of these cases is not understood, and there is little reason at the present time to believe that a viral agent is involved.

LYMPHOCYTIC CHORIOMENINGITIS

This disease is also called acute aseptic meningitis. It is endemic in character and the symptoms are essentially those of acute meningitis. Headache is a very prominent symptom. Epidemics have not been encountered in man. The virus attacks not only the nervous system, but may cause an influenza-like picture or an acute leukemia-like picture. The *mortality rate* is low. *Transmission* may be by contact with the virus in the droppings and urine of infected house mice.

Diagnosis in man depends upon the symptoms and signs of acute meningo-encephalitis with findings of an increased spinal fluid pressure and increased spinal fluid cell count. Lymphocytes predominate, and may vary from 200 to 2000 cells per cubic millimeter. No organisms are seen on stained smears and the spinal fluid shows a normal glucose content with normal or high protein. Diagnosis finally rests upon isolation of the virus from the blood, spinal fluid, spleen or brain and the development of neutralizing antibodies and complement-fixing antibodies. The *natural reservoir* for this disease is house mice and, questionably, dogs.

PROPHYLAXIS—The exclusion of mice from the living quarters and storage of food supplies to prevent contamination with mouse droppings or urine are the only known means of prophylaxis.

TREATMENT—This is entirely symptomatic.

PEDIATRIC EMERGENCIES*

CHARLES C CHAPPLE, MD†

THE purpose of this symposium is to bring to those carrying the heavy burden of professional service at home a better understanding of the conditions with which, perhaps, they have had but limited recent experience, but for which they are now called upon to give adequate treatment. Therefore it is the intention to cover in this brief synopsis the differential diagnosis and treatment of certain common conditions which, ordinarily, might or might not be considered pediatric emergencies.

PREMATURITY

The prematurely born infant, to accept a common definition, includes all infants under 5½ pounds in weight. As the primary consideration in its care, extra warmth must be supplied such an infant unless the room temperature is 85° F or more. High humidity also is desirable. Care must be taken that the heat surrounding the infant is not too great, or his body temperature will climb above normal. Heat can be supplied best by an incubator. These devices vary in complexity, but for home use simple models are available. Their specifications can be obtained from the Children's Bureau, Department of Labor, Washington, D C. The premature infant is particularly susceptible to infections, therefore the nurse must wear a mask besides taking the usual care in scrubbing.

The premature infant can tolerate as high a caloric intake per pound of body weight as a normal baby. Breast milk is the most desirable food, but evaporated milk and sugar can be substituted when breast milk is not available. The proportion will be discussed in a later paragraph on feeding. The feeding schedule for a small infant must have shorter intervals between nursings than

* From the Department of Pediatrics, School of Medicine, University of Pennsylvania, and the Children's Hospital of Philadelphia.

† Associate in Pediatrics, School of Medicine, University of Pennsylvania, Associate Pediatrician, Hospital of the University of Pennsylvania and the Children's Hospital of Philadelphia.

for a full term baby. For a very small infant it is sometimes necessary to give the feedings as frequently as every two hours. When practicable it is not unwise to feed him whenever he cries, thus giving frequent small feedings.

Vitamin K is of particular importance to the premature infant and should be given immediately after his birth. Vitamin C is the most important of the vitamins to be fed the baby regularly. The premature infant requires twice the amount of this vitamin that suffices the normal infant so he should be given 100 mg per day as early as he is able to take it. Vitamins A and D should be added to the dietary by the time the infant is ten days old. These are best given in a cod liver oil concentrate and started at one drop, increasing one drop daily until an adequate intake is reached. This quantity should approximate that required by a normal full term infant. Vitamin B, also in concentrated form, should be started with one drop when the optimum of A and D is reached. Iron, despite the physiological anemia, should be avoided in infants under 5 pounds as they are unable to assimilate it. At that weight, however, it should be started in a liquid form as in Elixir Feosol, beginning with one drop a day and increasing until an adequate quantity is given, or the appearance of black in the infant's stool shows that it is not all being utilized. Occasionally, too, iron will cause a loss of appetite in which case it should be reduced to an amount which does not produce symptoms.

CARE AND FEEDING OF THE NORMAL INFANT

Before proceeding to a discussion of abnormalities it might be wise to mention a few facts concerning the normal infant. He can see, hear, and has his other senses at birth though for his first four months he utilizes them but little. Until that time he is largely unaware of the outside world. He cries only when he is hungry, wet, or otherwise uncomfortable. He may have ten or more small stools a day, or, especially when breast fed, he may have one every third or fourth day only. He may regurgitate a little after feedings or even vomit occasionally, when he has been handled more than usual. He probably will require a feeding every fourth hour, but if he is small he may demand it more frequently. One cannot be arbitrary about the schedule though regularity is desirable. Until the infant weighs 9 pounds

he usually needs a 2 A M nursing If he sleeps through the night there is no need to insist upon this in a well baby At five months of age he probably will be willing to drop the 10 P M feeding, and at a year he will go on three meals a day.

Breast feeding is the most desirable feeding for all infants It does not disagree with more than one in a hundred, and it seldom if ever needs milk analysis When breast milk is not available a thoroughly reliable clean, uniform formula can be made of evaporated milk and sugar The infant's tolerance to evaporated milk is greater than to other forms of cows' milk because of the duration of the heating it has undergone When evaporated milk causes digestive symptoms, pasteurized goats' milk, or certain synthesized proprietaries should be substituted since the difficulty is almost certain to be due to milk allergy.

An infant's requirements are covered by 50 calories and approximately $2\frac{1}{2}$ ounces of fluid per pound of body weight. The calculations of proper formulas are simple Of the required calories, two thirds should be supplied by the milk which is 40 calories per ounce (if evaporated milk is used) and one third by the sugar which is 120 calories per ounce Boiled water is added in a sufficient quantity to meet the fluid requirements The minimum quantity of water to be added to a large can of evaporated milk ($13\frac{1}{2}$ ounces by volume) is 17 ounces If the formula is to be made of pasteurized milk (20 calories per ounce), the milk should be boiled hard for three minutes and the "skin" which has formed on cooling removed Raw unboiled milk has no place in any dietary, but it can be made safe by boiling The choice of sugars includes syrups of which Karo is an example, honey, granulated sugar, and proprietaries Ordinarily the choice between them is one of flavor or some other practical consideration At three to four months, vegetables may be given at the third meal Liver soup preparations are a good meat source for the infant, and may be added to the vegetables when he is taking the latter well It is wise to allow at least a week between the additions of new foods Egg may be started safely at seven to eight months and is given on alternate days with the meat Fruits and desserts are added at eight to ten months Vitamins should be added as recommended under the paragraphs on prematurity, and iron is a good adjunct for most infants

EXAMINATIONS

Examinations of infants should include orthopedic inspection. The normal infant has a physiological flat foot and should not be put into orthopedic shoes. Such shoes should be prescribed only for children whose difficulty in walking warrants them, but not prescribed routinely. The normal infant should be able, when lying on his back with thighs flexed on the abdomen and legs flexed on the thighs, to abduct his knees almost to the point touching the examining table. When abduction is possible only 45 or 50 degrees from the perpendicular, x-ray examination of the hips should be done as a precautionary measure for congenital dislocation of the hip. Under three months of age this may be the only sign present of this condition but at this age shortening, as well, becomes evident and is demonstrated by the asymmetry of the gluteal knee and ankle folds.

IMMUNIZATIONS

Vaccination for smallpox may be given at any time after birth, preferably before seven months of age since reactions during early infancy are not severe. Inoculations of whooping cough vaccine containing 10 to 20 million killed bacilli per cubic centimeter should be administered to a total of 7 cc. in three inoculations divided 1 cc. in each arm or leg on the first occasion, and 1.5 cc. in each at a different site on the second and third. For diphtheria prevention, alum-precipitated toxoid, 0.5 or 1 cc. depending upon its strength, should be given monthly for three doses. Tetanus toxoid may be combined with the diphtheria toxoid and given in the same inoculation. While tetanus prevention is not entirely dependable as complete protection from infection developing in a severe wound later in life, it obviates the necessity of giving the tetanus antitoxin for every minor injury. Instead, a further dose of the toxoid should be given in the event of a wound requiring tetanus protection, except when the wound is severe enough to warrant giving both toxoid and antitoxin.

All the specific immunizations should be completed before the child is one year old, although they are not contraindicated thereafter. Scarlet fever inoculations are of questionable value. Measles and mumps have no specific preventives except for the transient passive immunities (of two to three weeks) following

any of the injections mentioned subsequently under the specific diseases.

In the discussion of abnormalities which follows, an attempt will be made to group the conditions according to systems and to consider them as chronologically as possible

GASTRO-INTESTINAL DISORDERS

Constipation seldom requires serious consideration. The cause is usually dietary, although it can be caused by atony or spasticity of the large intestine and the diagnosis established by large, soft, stools, or by small, rabbit-like, hard stools. An increase in the carbohydrate content of the formula or a change to a less refined sugar will frequently relieve it. Prune juice and milk of magnesia are useful adjuncts. Castor oil seldom, if ever, should be used.

Colic is pain and as such is a symptom, not an entity. Its most frequent cause is underfeeding, but gastro-intestinal disturbances may cause it. An additional feeding will usually relieve the distress but an enema should be given if the taking of food does not stop the attack immediately. A thorough examination for other causes of pain should be made.

Intussusception begins as an attack of colic which is promptly accompanied by projectile vomiting and all the symptoms of acute intestinal obstruction, including shock. An enema, given immediately after the onset, with the enema bag held 3 to 5 feet above the infant and the patient's buttocks held tight together in order to retain the water, will frequently overcome the beginning intestinal invagination. Once invagination is established an enema will reveal mucus and blood, and immediate operation is the only course to be chosen.

Pyloric stenosis and *pylorospasm* are to be suspected in the presence of continual projectile vomiting in early infancy. Although the former usually appears in boys and the latter in girls, this is not always the case. Visible peristalsis, after feedings, may be demonstrable in either condition. Constipation and infrequent urination follow as a result of the small quantities of food retained. All symptoms are likely to reach their peak at six weeks of age. Pylorospasm can be relieved by atropine which is most easily given as tincture of belladonna, 1 minim in a teaspoonful of water fifteen minutes before feedings. This dose

can be increased 1 drop at a time until flushing of the face is produced and then reduced to the maximum safe level. Atropine may be continued regularly as long as necessary. Pyloric stenosis requires operation, but a diagnostic trial of atropine and thickened feedings, made by the addition of 5 to 10 per cent cereal to the formula, should be given first.

Appendicitis occurs frequently throughout childhood. Its signs are the same as in the adult. Rectal examination is invaluable as a diagnostic measure.

Teething frequently causes symptoms which include swollen gums and fever. Additionally, it lowers the resistance of the infant to a point where he becomes susceptible to minor infections. Incision of the gum over the tooth is indicated rarely but is at times helpful.

Gingivitis yields to gentian violet, 1 per cent aqueous solution, and (in older children) to mouth washes of hydrogen peroxide and zephiran. In very severe cases the application of a direct stream of oxygen for prolonged periods is of benefit in preventing noma.

RESPIRATORY TRACT DISEASES

Colds are of no more serious import in otherwise healthy infants than in older children. Suction of mucus from the nares of infants can be accomplished with an ordinary bulb syringe. This procedure, done frequently by the mother, adds greatly to the baby's comfort.

Tonsillitis is a self-limited disease usually causing a high temperature for two or three days. *Otitis media* may complicate it, but treatment for the tonsillitis itself is usually limited to small doses of aspirin given occasionally to control the fever.

Otitis media is a common complication of colds and of teething. Treatment should be directed toward the opening of the eustachian tube by means of astringent drops such as 0.5 per cent ephedrine hydrochloride instilled into the nose when the baby is lying flat on its back. Additionally, heat, preferably in the form of light, should be applied to the ear itself. An efficient, simple heater can be made by cutting the bottom of a round can or container so that it will fit around the socket on an extension cord. The smallest bulb available should then be screwed into the socket through the open end of the can. This

any of the injections mentioned subsequently under the specific diseases

In the discussion of abnormalities which follows, an attempt will be made to group the conditions according to systems and to consider them as chronologically as possible

Gingivitis yields to gentian violet, 1 per cent aqueous solution, and (in older children) to mouth washes of hydrogen peroxide and zephiran. In very severe cases the application of a direct stream of oxygen for prolonged periods is of benefit in preventing noma.

RESPIRATORY TRACT DISEASES

Colds are of no more serious import in otherwise healthy infants than in older children. Suction of mucus from the nares of infants can be accomplished with an ordinary bulb syringe. This procedure, done frequently by the mother, adds greatly to the baby's comfort.

Tonsillitis is a self-limited disease usually causing a high temperature for two or three days. *Otitis media* may complicate it, but treatment for the tonsillitis itself is usually limited to small doses of aspirin given occasionally to control the fever.

Otitis media is a common complication of colds and of teething. Treatment should be directed toward the opening of the eustachian tube by means of astringent drops such as 0.5 per cent ephedrine hydrochloride instilled into the nose when the baby is lying flat on its back. Additionally, heat, preferably in the form of light, should be applied to the ear itself. An efficient, simple heater can be made by cutting the bottom of a round can or container so that it will fit around the socket on an extension cord. The smallest bulb available should then be screwed into the socket through the open end of the can. This

simple reflector can direct the light and heat into the ear and be applied safely as long and frequently as is required for the relief of pain. In infants, care must be taken that too great heat is not developed. Such a heater can be used not only for the pain of the acute ear, but also to shorten the course of a draining ear. The sulfonamides should be considered if the condition warrants it, and with these, low dosage ordinarily suffices.

Croup is a laryngitis with sufficient edema and spasm to cause obstructive dyspnea. It yields to steam inhalations and the use of an expectorant. The onset of croup as a rule, is sudden. A child with a barking cough suddenly has difficulty in breathing. When this occurs the child should be taken into the bathroom where hot water can be run into a tub to produce a steamy atmosphere. Syrup of ipecac, 5 minims, should be given directly onto the tongue at intervals of one-half hour or less if the symptoms persist, or until vomiting is produced.

Pneumonia in childhood may be difficult to detect in the first two days after its onset. However, if there is a high fever, a respiratory rate greater than 40 per minute, and a cough, it is a reasonably sure presumptive diagnosis, although physical signs will reveal only a moderate suppression of breath sounds over the involved area which may be small. Sulfathiazole or sulfadiazine should be given in dosages up to $1\frac{1}{2}$ grains per pound of body weight in twenty-four hours. When sulfadiazine, particularly, is used, one-half the dose for twenty-four hours can be given initially. Sulfonamides in general are better tolerated when soda bicarbonate is given simultaneously in approximately the same dosage. It is important when giving sulfonamides to be certain that an adequate urinary output is maintained.

Atypical or so-called "*virus*" *pneumonia* at this time appears to include in a group of protracted pneumonias all those which are sulfonamide resistant. Specific therapy beyond the use of convalescent serum is unavailable.

GENITO-URINARY DISORDERS

Pyelitis is much more common in girls than in boys. Daily temperature rises as high as 104° F are usual. In the first few days of fever, white cells may not appear in the urine, but the diagnosis cannot be definitely established until they do. Ideally a catheterized specimen is examined. Fluids and alkalies, especially sodium citrate, are ordinarily sufficient treatment. More

severe cases require alternation between alkali and acid-producing medications. One of the sulfonamides may be indicated. A prolonged course, or frequently repeated attacks, warrants a thorough examination of the genito-urinary tract.

Boys occasionally have an infection in the presence of phimosis which at first resembles a nonspecific urethritis, but which in reality is limited to the external surface of the glans. Frequent bathing of the glans with a mild antiseptic solution, followed by hydrogen peroxide, will check the process.

Gonorrheal vaginitis is a local infection in girls before puberty which does not spread to the fallopian tubes. The use of the estrogenic hormone, when possible in the form of vaginal suppositories, is indicated. Additionally, sulfadiazine should be given by mouth.

EXANTHEMS

Roscola infantum is a mildly infectious disease occurring in infants under three years of age. A fever, usually accompanied by a mildly red throat, is the only sign present until, on the fifth day, a mottled, nondescript rash appears. With its appearance the child recovers. The disease requires no treatment beyond aspirin to control the temperature.

Measles may occur at any time after six months of age. Its incubation period is from ten days to two weeks. Coryza, the first symptom, soon develops into photophobia accompanied by a severe cough. If Koplik spots are present they confirm the diagnosis, but they do not always appear. These are white, sand-like spots with a small red areola around them on the gums near the buccal margin. The rash which usually follows the Koplik spots by one to two days and onset of the coryza by three to four days, begins about the lobe of the ear and the upper part of the neck and the lower part of the face, spreading rapidly to the rest of the body, and is composed of coppery red spots, which vary from the size of a split pea to that of a quarter, with areas of normal skin between them. Treatment is nonspecific and consists of keeping the patient in a darkened room as long as light hurts his eyes, aspirin and other coal tar derivatives to assist in his comfort, and cough mixtures. Complications are usually limited to otitis media, but may include pneumonia. During the course of severe measles, rales can be heard throughout the chest regularly.

Measles from a known exposure can be prevented or modified to allow the production of active immunity without suffering a severe attack. Such prevention or modification is achieved by the administration of intramuscular blood from a person who has had the disease in childhood, pooled adult serum, placental extract, or gamma globulin obtained from plasma fractionation by the method of Cohn. When blood is to be given, it need not be matched since it is injected intramuscularly. Inoculation should be given before the fifth day after exposure. Active immunity by means of an attenuated measles virus is being tested experimentally but vaccines of this type are not as yet available.

Scarlet fever has an incubation period of forty-eight hours to ten days. Its onset is frequently accompanied by vomiting. An edematous, red throat and heavily coated tongue bordered in bright red are always present when the disease is established. The rash is a blush with a goose-flesh appearance. This is evident behind the ears, on the flexor surfaces, and most strikingly on the lower abdomen. It avoids the region about the mouth, which consequently looks pale. Complications, though not common, are severe and include cardiac and renal involvement. Prevention following a known exposure can be accomplished by the administration of convalescent serum, which is also of value in treatment. Sulfanilamide or sulfadiazine may be used to advantage.

Chickenpox is a mild disease which has rare complications and needs treatment only for the itchiness (calamine lotion) and rarely to prevent secondary infection of the vesicles. Its incubation period is approximately two weeks. At the end of this time the vesicles, filled with clear fluid, appear on the trunk. For five days they increase in number during which time the earlier ones have become purulent. These lesions occur largely on the covered areas of the body, although occasional ones occur on the hands, feet and face.

Smallpox resembles chickenpox, but the lesions occur in greater numbers on the exposed parts, and frequently become confluent. Absence of recent vaccination, history of exposure, the uniform lesions not appearing in the crops which are characteristic of chickenpox, and a much more severe course, are the distinguishing factors between this disease and chickenpox.

OTHER COMMUNICABLE DISEASES

Mumps occurs at any time after the second year of life. Before adolescence it is almost free of complications. Treatment is limited to ice packs locally and aspirin. After puberty orchitis is very common. Convalescent serum is of questionable value in treatment but may have value as a preventive measure. It certainly has much less striking effects than specific convalescent sera in the prevention of measles and scarlet fever. Orchiotomy, incision of the tunica albuginea, by releasing the pressure caused by the orchitis, offers promise in the prevention of testicular atrophy.

Whooping cough occurs at any age. The cough, which is usually worse at night, is characterized by an increasing number of coughs between inspirations, and is frequently followed by vomiting. Diagnosis usually can be established bacteriologically in the early days of the disease, and by the end of the third week by the appearance of a lymphocytosis. Treatment consists of expectorants to thin theropy mucus. Diet should consist of small frequent feedings. Cough mixtures and sedatives are of little value. X-ray treatments of the trachea occasionally help. In infants under one year, in whom the mortality is very high, hyperimmune convalescent serum as treatment has produced excellent results. Preventive inoculations should be given all infants routinely.

Diphtheria is a disease which should not be encountered except in very young infants who have not yet received preventive inoculations. It is characterized by a gray adherent membrane on the pharynx, bloody serous discharge from the nose, or increasing obstructive dyspnea. Diagnosis must be corroborated bacteriologically. Treatment is accomplished by antitoxin.

Meningitis can be caused by many different organisms. The symptoms in all cases, however, are similar. Stiff neck, increased or decreased knee jerks, headache, fever, are common to all. Brudzinski's sign is a reliable indication of early meningeal involvement. A spinal tap, followed by a complete examination of the fluid obtained, is necessary for corroboration of the diagnosis. *Meningococcus meningitis* responds well to sulfonamide therapy. Other types may or may not respond, depending upon the causative organism. However, many cases of the previously fatal influenzal meningitis have now recovered under this treat-

ment. Serum and symptomatic measures may be required as well

Anterior poliomyelitis has no known preventive. It is recognized by the occurrence of meningeal signs following a normal interval of several days after a preliminary low fever. A gastrointestinal disturbance or symptoms of an upper respiratory tract infection may have been present during the first low fever. The meningeal signs are usually accompanied by pain and tenderness of the extremities and elsewhere. Its transmission may be by one of several routes—contaminated food or water, inhalation of the virus, direct contact and insect bites. The treatment which appears the most promising is the Sister Kenny regimen and possibly in addition the cautious use of prostigmine.

MISCELLANEOUS

Convulsions are symptoms. They may occur at the onset of any disease in childhood. Frequently temperatures of 105° F and above will produce them. Treatment should deal with the reduction of the temperature by means of ice packs to the head, cooling sponges or baths, and the diagnosis of the underlying pathology. In the absence of high fever, hypoglycemia is a possible cause. In early infancy, tetany of hypocalcemic origin must be considered. As treatment, saline and 5 per cent glucose infusions are of value in either case. Determinations of the blood levels of calcium and of blood sugar will be necessary to distinguish them. Dietary adjustment, with emphasis on an increase of protein content, should prevent wide blood sugar fluctuations. Calcium gluconate intramuscularly, for the acute phase, to be followed immediately and continuously by large doses of vitamin D, should prevent the recurrence of convulsions from tetany. Allergies and gastro-intestinal disturbances sometimes cause convulsions.

Meningismus is a rigidity of the neck sometimes associated with increased knee jerks and is a symptom, not an entity. It may be present as a complication of pyelitis, adenitis, and other infections. The spinal fluid may have an increased number of cells and be under increased pressure. Negative bacteriological examination of this fluid and the determination of an underlying cause are necessary to establish the diagnosis. Treatment is directed toward the underlying condition.

THE RECOGNITION AND MANAGEMENT OF CARDIAC EMERGENCIES

REYNOLD S GRIFFITH M.D.*

IN consideration of the title of this clinic, the question naturally arises, what is a cardiac emergency? Actually, any acute or chronic cardiovascular disease manifesting symptoms of acute cardiac distress may be included in this classification. Space would not permit such a general consideration so by necessity this discussion will be limited to those emergencies which are most commonly encountered.

A definite increase in the incidence of cardiovascular disease may be expected both in the civil population and military personnel either directly or indirectly as a result of the war. Acute infectious diseases, malnutrition, nervous and physical strain, are important contributing factors. Such conditions not only are conducive to the development of cardiovascular degeneration but predispose to acute exacerbation of pre-existing diseases. Already an increase in acute cardiac accidents has been reported from several war plants, especially in the older age groups which have been called back from retirement or sedentary activities. Those with previous vascular and myocardial degeneration manifest evidence of failure either by a gradually progressing myocardial weakness or by an acute collapse. The most common accidents are a result of coronary artery disease such as angina pectoris or coronary occlusion.

ANGINA PECTORIS AND CORONARY OCCLUSION

The pain of angina pectoris and coronary occlusion is due to myocardial ischemia which results from a partial or complete occlusion of a coronary artery or one of its branches. The lumen of the vessel may be obstructed gradually by an arteriosclerotic plaque or suddenly by thrombosis or embolism. Syphilitic

* Assistant Professor of Medicine, Jefferson Medical College. Assistant Physician, Jefferson Hospital.

lesions in the wall of the aorta may encroach upon the orifice of a coronary artery. In either case there is a gradual or sudden obstruction of the blood supply to a portion of the myocardium.

A gradual obstruction may occur without pain, and may be manifested by no other symptoms than those commonly associated with myocardial weakness and failure. The victim first notices dyspnea resulting from physical tasks that were formerly accomplished without effort. Over a period of years he notices increasing breathlessness on slight exertion as the blood supply to the heart muscle is gradually and progressively impaired.

During the stage of partial occlusion, a sudden strenuous physical effort or mental excitement may result in a sudden severe pain of angina pectoris—the angina of effort. The amount of exercise necessary to provoke a pain usually decreases as the obstruction increases. The partially obstructed vessel which supplies sufficient blood during rest causes a partial ischemia when a greater volume is required during effort. It is not uncommon for such cases to be terminated by complete coronary occlusion. The pain of angina pectoris is variable in location and intensity. It may remain localized under any part of the anterior chest wall, but frequently it radiates down the inner surface of the left arm, less often the right arm. In fact, the pain may be entirely localized in the left shoulder, elbow, neck, or face. Numbness, tingling, and other sensory disturbances in the left arm, hand, or fingers may accompany the pain or be the only complaint. The intensity may vary from a slight indefinite sensation to an excruciating “viselike” pain.

Treatment

The pain of angina pectoris is of short duration, from a few seconds to a few minutes. Often it is readily relieved by discontinuance of all muscular effort. Amyl nitrite, 3 minims, by inhalation, or a tablet of glyceryl trinitrate (nitroglycerin), $\frac{1}{100}$ grain (0.6 mg), placed under the tongue will give immediate relief. The latter is more convenient to administer and the effect is equally as prompt. The ampules of amyl nitrite are more costly, and its vapor permeates the air to the annoyance of all persons in the room.

Nerve sedatives have a beneficial influence in that nervous

tension is reduced and sleep is aided. Phenobarbital, given in $\frac{1}{2}$ -grain (32 mg) doses three or four times a day, is convenient to use over a long period of time. Sodium bromide, 5 to 10 grains (0.3 to 0.6 gm), four times per day, often proves of value when the other sedatives fail.

Papaverine hydrochloride administered in $1\frac{1}{2}$ -grain (0.1 gm) doses, four times daily, may reduce the frequency and severity of the attacks.

Good results have been reported following the intramuscular injection of testosterone propionate dissolved in sesame oil. Lesser used 25-mg doses every second to fifth day, depending on the frequency and severity of attacks, for a total of five to twenty-five injections. He reported no untoward reactions and all patients improved.

It is essential that the patient change his type of work to correspond with his ability to do it without pain. In fact he soon learns from experience the amount of physical effort that he can tolerate before pain appears. If the patient is overweight it is to his advantage to reduce the excess. Likewise, he should avoid large meals whether he is overweight or not. The added load on the circulation of digesting and assimilating a large meal often results in an attack of angina. In fact, deaths from such excesses are not uncommon, and in the past were usually reported as acute "dilatation of the stomach."

It is generally agreed that cigarette smoking is deleterious, alcohol, to the contrary, in moderate amounts is not injurious and in many cases affords relief from attacks of pain. Actually, the best outlook is for the patient who is willing to eliminate all excesses and reduce the strain of living to a minimum. This should include adjustment of his physical, financial, sexual and mental loads.

Surgical procedures such as total thyroidectomy and paravertebral injections of alcohol intended for the relief of intractable pain of angina pectoris require careful selection of cases and very often are attended with a great deal of risk. They should be attempted only by those especially trained in the technique.

CORONARY OCCLUSION

It is not uncommon for the attacks of angina pectoris to terminate in coronary occlusion, although in many instances the

attacks of pain may disappear entirely after the patient begins to show evidence of myocardial insufficiency. Likewise, the pain may recur after the myocardium regains its former tone.

The site and the character of the pain of coronary occlusion is just as variable as the pain of angina pectoris. It may be centered entirely in the epigastrium. In this location it has been confused with acute upper abdominal emergencies, occasionally leading to surgical exploration. The frequently associated symptoms of nausea, vomiting, leukocytosis and fever contribute to the picture.

The duration and intensity of pain vary in wide limits. In general, a pain lasting for more than fifteen minutes is suspicious of coronary occlusion. The intensity varies from a slight retrosternal oppression to an excruciating, prolonged constriction with a feeling of impending dissolution. The pain due to angina pectoris is almost always associated with an elevated blood pressure. If the blood pressure falls soon after the pain begins, coronary occlusion must be suspected. However, the fall in blood pressure may be delayed for several hours or even a day. The degree and rapidity of fall largely depend upon the severity of the attack. The pulse rate usually remains unchanged during the pain, the temperature may increase one or two degrees accompanied by a leukocytosis of 12,000 to 18,000. After a few hours the rate of sedimentation of the red cells becomes increased, although this may be delayed for several days. A pericardial friction rub may be heard if the infarct involves the anterior ventricular surface. The heart sounds may become fainter. Gallop rhythm and frequent premature beats may be present although the heart sounds often reveal no perceptible change.

The changes in the electrocardiographic pattern usually confirm the diagnosis, occasionally such changes are delayed or absent in the ordinary leads. Recently the American Heart Association recommended multiple chest leads in all cases suspected of having myocardial infarction.

The Management of Coronary Occlusion

The immediate treatment of myocardial infarction consists of the adoption of all methods to reduce the work of the myocardium to the absolute minimum. Rest should be enforced and it should be continued for four to six weeks. The use of the

bed pan and urinal should be insisted upon. However, in the case of very obese patients, the use of the bed pan may require more physical exertion than the use of a commode arranged near the bed.

Pain is best relieved by morphine in $\frac{1}{4}$ -grain (16 mg) doses repeated as often as necessary. Pantopon, $\frac{1}{3}$ grain (20 mg), or dilaudid, $\frac{1}{12}$ grain (5 mg) may be used in the same way. Papaverine hydrochloride in $1\frac{1}{2}$ grain (0.01 gm) doses has been found effective when administered intravenously. Papaverine is used for its antispasmodic action on the coronary arteries. Its analgesic effect is negligible in therapeutic doses. Atropine sulfate has been found of value to counteract the action of the vagus which induces reflex spasm of the other coronary vessels. The usual dose is $\frac{1}{100}$ grain (0.6 mg), repeated several times a day. Atropine is contraindicated if the heart rate is rapid.

The inhalation of oxygen is a life-saving measure and often affords relief from pain, dyspnea and cyanosis. The concentration of oxygen in a tent should be maintained at 50 per cent or higher. This requires an oxygen flow of at least 9 liters and preferably 10 liters per minute. For relief of pain or circulatory failure, higher concentrations may be required. Such concentrations may be obtained by use of the B.L.B. or Barach-Eckman masks.

Cardiac arrhythmias complicating myocardial infarction add to the seriousness of the condition. Frequent ventricular premature beats may initiate fibrillation of the ventricle. Ventricular tachycardia, which is less common, may result in myocardial failure. Either condition can be controlled by the administration of quinidine sulfate, 3 grains (0.2 gm), every three hours. Quinidine is a myocardial depressant and it must be used with great caution.

Digitalis should be used only when signs of myocardial failure are evident. The increased force of ventricular contraction produced by digitalis may result in myocardial rupture. Also, its use in full doses may initiate arrhythmias which result in ventricular fibrillation.

ACUTE LEFT VENTRICULAR FAILURE

Dyspnea is the cardinal symptom of left ventricular failure. Usually it appears only after exertion, but it may appear while

the patient is at rest, or even awaken him from a deep sleep. It may be periodic, transient, or persistent. In fact, the initial warning may be a severe attack of paroxysmal nocturnal dyspnea with pulmonary edema. Various conditions such as vascular hypertension and chronic valvular defects, which add a great load to the work of the left ventricle, are predisposing factors which often lead to failure.

Primary acute right ventricular failure is comparatively uncommon and usually it is secondary to chronic pulmonary disease, embolism, or pneumonia. It is more often seen in conjunction with left ventricular failure due to conditions which cause degeneration of both sides of the heart. Arteriosclerosis, hypertension, syphilis and chronic rheumatic valvular disease are the most common predisposing factors.

Frequently mild attacks of nocturnal dyspnea are mistaken for bronchial asthma. Such attacks may be repeated for several months before their true origin is recognized. In other instances, however, the first indication of serious cardiac disease may be a severe paroxysm of nocturnal dyspnea with pulmonary edema. The patient suddenly awakens with a feeling of suffocation and coughs frothy, blood-stained sputum. The fluid accumulates rapidly in the lungs and bronchi causing loud gurgling rales. The skin becomes cold, moist and cyanotic. The pulse is rapid and the blood pressure falls. Recovery from such attacks is not uncommon, and they may or may not be repeated.

Treatment

No single measure is more successful in this emergency than the injection of $\frac{1}{4}$ grain (15 mg) of morphine sulfate. Usually its administration is followed by the immediate relief of the anxiety, cough and dyspnea. Frequently no other treatment is necessary except rest for several weeks. If signs of myocardial insufficiency persist, the prompt use of digitalis is indicated. It may be given by mouth, $4\frac{1}{2}$ grains (0.3 gm), at six-hour intervals for four or five doses. If more rapid action is desired, digitaline Nativelle by oral administration of a total of from 1.25 to 1.5 mg given in fractional doses, 0.25 to 0.5 mg at intervals of from four to six hours. Ouabain (G-strophanthin) may be administered intravenously if still more rapid action is desired. The dose for intravenous use is $\frac{1}{250}$ grain (0.25 mg). Neither

of these preparations should be used if the patient has had digitalis previously

Venesection is useful to relieve the load on the right ventricle by decreasing its output. The same effect may be obtained by applying tourniquets to the four extremities. These should be released alternately every few minutes. This procedure traps the venous blood in the limbs, consequently prevents its return to the right side of the heart. Oxygen is a valuable aid in preventing the deleterious effects of anoxia on the tissues. It should be administered by means of a mask to obtain a concentration of 70 to 100 per cent. Such concentrations have been found to be highly beneficial in emergencies. However, many patients will object to the tightly fitting mask. The tent is more comfortable for the prolonged administration of oxygen, and valuable in an emergency if it is readily available. A concentration of 50 per cent can be maintained within a tent if the flow is regulated to at least 9 and preferably 10 liters per minute. To obtain maximum benefits from oxygen therapy, the oxygen concentration of the air in the tent should be tested at frequent intervals. The temperature and humidity in the tent should be regulated to the patient's comfort.

In the absence of other equipment in an emergency, oxygen may be administered by means of a nasal catheter passed into the nasopharynx. A concentration of nearly 40 per cent may be obtained by this method. The oxygen should be passed through at least 3 inches of water to moisten the gas and prevent drying of the mucous membranes. Ordinary industrial oxygen is the same as oxygen used in medical practice.

Aminophylline, 3 grains (0.2 gm), may be used to prevent attacks of nocturnal dyspnea. However, the intravenous mercurials, salyrgan and mercupurin, have been found to be more effective and reliable. Their greatest value is found in the prevention of those attacks of nocturnal dyspnea associated with chronic congestive heart failure. In such cases they should be used in conjunction with one of the acid-producing salts, such as ammonium chloride. This should be given in a total of 80 to 90 grains (5.3 to 6 gm) in divided doses each day for two or three days prior to the intramuscular or intravenous use of the mercurial.

Following recovery from an acute attack of nocturnal dysp-

nea, the routine treatment for myocardial insufficiency should be followed for two to four weeks

Attacks of acute ventricular failure are often precipitated by the added strain on the left ventricle as a result of surgical operations or acute illnesses. The modern custom of overloading the circulation by the administration of large volumes of saline and glucose solutions before, during, or after operation is often the final straw. Such fluids should be given slowly and in moderate amounts, as needed. The routine postoperative care should be abandoned, and individual care ordered when the patient presents any evidence of left ventricular weakness, or any of the conditions which predispose to it. Either during an acute illness or in the postoperative period, a constant watch should be kept for signs of left ventricular strain. Early signs consist of crepitant rales at the bases of the lungs, increasing pulse and respiratory rates. The early and judicious use of digitalis and oxygen will prevent a more serious, if not a fatal collapse.

PAROXYSMAL TACHYCARDIAS

These conditions are recognized by their abrupt onset and termination, and their great regularity. During a paroxysm the rate may vary from hour to hour but there is no variation between the beats. These ectopic rhythms may originate either in the auricle, the A-V node, or the wall of the ventricle. Their exact origin can be determined only by means of an electrocardiographic tracing. Paroxysmal tachycardia of ventricular origin is usually associated with organic heart disease, but it may be induced by toxic doses of digitalis. The commoner varieties—auricular and nodal tachycardias—usually occur in otherwise normal hearts. The duration of the attacks may be short and frequently repeated, or they may continue for several days.

Treatment

Many attacks are of such short duration that no treatment is required. In the more severe episodes, the patient is greatly distressed by the tumultuous heart action and several methods may be attempted before one is successful. All methods of treatment depend upon the same principle—stimulation of the vagus. Patients who have had repeated attacks often learn a

simple method which is effective in controlling the attacks in their particular cases. Such procedures include a forcible attempt to expire, after deep inspiration with the glottis closed, or an attempt at inspiration under the same conditions. Either method should be repeated several times until successful. Induced vomiting is often successful, this may be accomplished by use of an emetic drug such as syrup of ipecac, 2 fluidrachms (8 cc), or by irritation of the glottis with the finger or other object. Pressure on the eyeball may be effective. Stimulation of the carotid sinus by means of pressure with several fingers is more certain. The carotid sinus is located approximately at the level of the upper border of the thyroid cartilage. Pressure should be applied by means of two or more fingers over the right carotid artery, if unsuccessful the procedure should be repeated on the left side.

Several drugs having a vagomimetic effect have been used, and in certain cases any one of them may be effective when others fail. Acetyl-beta-methylcholine chloride (mechoyl) in the dose of 5 to 50 mg by subcutaneous injection often gives prompt relief. The small dose should be tried first. Large doses may cause profuse sweating, salivation and lacrimation. If these ill effects become alarming they are promptly controlled by the hypodermic administration of $\frac{1}{100}$ grain (0.6 mg) of atropine sulfate.

The hypodermic injection of prostigmine methylsulfate, 1 cc of a 1:2000 solution, has been found to be effective in certain cases. Physostigmine salicylate has a similar action but it is not so effective.

If the attack persists, quinidine sulfate may be used. It should be given in 3-grain (0.2-gm) doses every two or three hours, after a single initial dose to test for sensitivity to the drug. Recently Sturnick and his associates (J.A.M.A., 1943) prepared a soluble preparation of quinidine suitable for parenteral administration for treating acute cardiac arrhythmias when vomiting, collapse, or unconsciousness precluded oral administration. They report excellent results in the treatment of paroxysmal tachycardia with this preparation.

In severe cases of tachycardia with impending myocardial failure, digitalis is indicated. It may be given by mouth in full doses, or if more rapid action is required one of the pure glucosides, strophanthin or ouabain, may be given parenterally.

HEART BLOCK (STOKES-ADAMS SYNDROME)

Stokes-Adams syndrome is included as a cardiac emergency because of the possibility of its sudden onset without previous warning. It must be stressed that the characteristic attacks with syncope and convulsions are extremely rare. There are many minor degrees of the condition, however, which may be manifested by a slight faintness or vertigo which passes off in a few seconds, or may be more prolonged and the patient falls unconscious. The severity of the symptoms depend upon the duration of the cerebral ischemia. This results from cessation of ventricular activity when the transition occurs from normal auriculoventricular conductions to complete block. In the severe attacks the appearance of the patient may have a striking resemblance to an epileptic seizure. The skin may be cold, moist and cyanotic. The veins become greatly distended. After the paroxysm, recovery is usually rapid, and without residual effects. This helps to distinguish it from an apoplectic attack in which there is persistent paralysis.

The diagnosis of Stokes-Adams syndrome is confirmed by the very slow heart rate, usually under 40 per minute, the brevity of the attack, and prompt recovery. Occasionally additional confirmation may be had by comparing the pulsations counted in the distended jugular veins, which correspond to auricular contractions, with the ventricular rate counted at the wrist or the apex of the heart. The electrocardiographic pattern is characteristic and the final word in the diagnosis.

Treatment

In most instances Stokes-Adams syndrome is so brief that no treatment is necessary. However, the frequency of attacks may be reduced by administering drugs which increase the excitability of the idioventricular pacemaker from which impulses arise in the absence of the normal auriculoventricular pathway. Epinephrine has been found to be effective in relieving the attacks. It should be administered hypodermically in 0.5- to 1-cc doses of the 1:1000 solution. Ephedrine sulfate may be used in the same manner, the dose is $\frac{1}{8}$ to $\frac{3}{8}$ grain (20 to 25 mg). It has the advantage of having a more prolonged effect, although it is not so powerful. Ephedrine sulfate is especially useful in preventing the recurrence of attacks. It should be

given by mouth in the same dose, three or four times daily. Its use may be continued for months or years if necessary.

Barium chloride, $\frac{1}{2}$ to 1 grain (30 to 60 mg) three times daily by mouth, is an older remedy and its value has not been confirmed by experience.

Atropine sulfate, $\frac{1}{100}$ grain hypodermically, may be used for the relief of an attack.

The underlying cause should receive proper treatment. In most cases this is coronary sclerosis or rheumatic endocarditis. The older idea that many cases were due to luetic heart disease with gummatous lesions encroaching on the bundle of His has not stood up in the light of modern investigation. Of course, if the blood Wassermann test is positive, the patient should receive proper antiluetic therapy.

EXTRACARDIAC VASCULAR EMERGENCIES*

DOUGLAS W LUND, M D

THE vascular emergencies arise from occlusion of vessels or rupture of vessels. In many diseases which are generally insidious or primarily extravascular, there may occasionally develop vascular abnormalities which are emergencies. It is not practicable, however, to deal with such exceptions in detail.

Hemorrhage is the escape of blood from the normal confines of the vascular system. It becomes an emergency when the total loss is great enough to interfere with the normal functions of an individual, or when the hemorrhage is into certain tissues, interfering with specific processes. This latter form of hemorrhage will be dealt with in relation to those organs where its occurrence, along with thrombosis, embolism and vasospasm, results in impairment of function indicative of the organ involved.

HEMORRHAGE

Gross blood loss may occur externally, where it is easily detectable, or internally, into a large body cavity, where it is concealed. In either case, the hemorrhage may produce the syndrome of shock, or if the blood loss is not excessive or rapid, it may simply produce a secondary anemia. Although there is individual variation, the rapid loss of 750 cc (approximately $1\frac{2}{3}$ pints) of blood may give evidence of approaching shock. A more gradual loss of blood will result in a fall in the erythrocyte count, and will usually produce no frank symptoms until far advanced.

Symptoms and Signs—Anemia secondary to hemorrhage is characterized by pallor, particularly of the mucus membranes. Generalized weakness and dizziness are frequent. The temperature may be subnormal at first and slightly elevated later. Complaints such as headache, syncope, nervousness or somnolence may result from the cerebral ischemia. The blood changes are, of course, diagnostic.

* From the Department of Medicine, Jefferson Medical College.

Despite the ability to observe external hemorrhage and to appreciate by the methods of physical diagnosis a collection of blood in a body cavity, excessive blood loss is frequently not suspected until signs and symptoms of approaching shock have occurred. The patient may complain of chilliness, insatiable thirst, or weakness. Pallor is an early and very constant sign due to constriction of the peripheral vessels. The veins are collapsed, and blanching following digital pressure disappears slowly. The skin, particularly of the extremities, is cold and moist. The nail beds and finger tips are pale. Restlessness may be severe, yet it may change rapidly to apathy and somnolence. The pulse rate is rapid and may become thready or imperceptible as shock advances. Diarrhea and enuresis are occasionally observed. Finally, the unfailing evidence of advancing shock is a progressive fall of blood pressure. The systolic pressure may be sustained for a considerable period above the critical level of 75 to 90 mm. of mercury. With continued bleeding the pressure will fall rapidly, resulting in a shock-like state and death.

Laboratory Diagnosis—Within a period of one-half to two hours following blood loss of several hundred cubic centimeters, there is often an elevation of the total leukocyte count and an increase in the younger leukocyte elements. A drop in the erythrocyte count and hemoglobin content occurs more gradually. Furthermore, the approach of shock is accompanied by hemoconcentration. This is more evident in that syndrome of shock where the loss of blood is not a factor. A patient bleeding rapidly may die with little fall in the erythrocyte count or hemoglobin concentration. Following severe hemorrhage, hemodilution is appreciable in a few hours and reaches a maximum in about forty-eight hours. Since this change permits the amount of blood loss sustained to be estimated at a later date, it is best immediately to obtain a complete blood count at the advent of hemorrhage and repeat this at appropriate intervals of from one to several hours.

Treatment

The initial objective in hemorrhage is the stemming of the loss of blood. Where a shock-like state is imminent it is necessary to replace the volume of blood by the intravenous or the

intrasternal route *Whole citrated blood* compatible with that of the patient is the fluid of choice. However, owing to the factors of availability and facility it may be necessary and prudent to use *plasma*. In shock resulting from hemorrhage, the isotonic plasma is best, but when concentrated plasma is more readily available, this may be used. The equivalent of 500 cc of whole blood is from 15 gm to 17.5 gm of plasma protein, i.e., about 250 cc of the undiluted plasma. In the treatment of severe hemorrhage, it may be necessary to give 2000 to 2500 cc of whole blood, or 4 to 5 units (15 gm to 17.5 gm. per unit) of plasma.

The use of isotonic salt solution, with or without glucose, is not advised, since the elements needing replacement are the plasma protein and erythrocytes. When the above solutions are not available, the following substances have been recommended: (1) human serum, which, due to less protein content, is less efficacious than the plasma, (2) purified human albumin, or (3) solutions of pectin, which are generally not available at the present time, (4) solutions of acacia which are rarely, if ever, indicated.

The *general measures* for hemorrhage are adequate sedation of the restless patient, and conservation of body heat. The application of heat exceeding normal body temperature is to be deplored, since the damage sustained by the tissues may of itself aggravate the syndrome of shock. Peripheral constriction is a mechanism by which the vascular system adjusts itself to the decreased blood volume. It is ill advised to interfere with this process by applying excessive heat to the point of overcoming this constriction.

The drugs which cause vasoconstriction (i.e., epinephrine, ephedrine, pitressin, benzedrine, and strychnine) have been advocated and are briefly efficacious, however, their use may be followed by a fall in blood pressure supposedly due to fatigue of the vasoconstrictory mechanism. The use of suprarenal cortical extract has not yet proved of practical value. If blood is being replaced, the inhalation of oxygen, or better, oxygen (90 per cent) and carbon dioxide (10 per cent) gas, would seem logical, in view of the tissue anoxia accompanying hemorrhage and shock.

There would seem to be little advantage in the old practice

of binding the limbs tightly, since elevation of the foot of the bed, with the head and thorax dependent, will provide the maximum of circulating blood to the vital organs

In summary, the treatment of hemorrhage (volume of blood lost) is (1) to stop the bleeding, (2) to replace the blood loss, (3) to conserve the body temperature, and (4) to allay restlessness

VASCULAR OCCLUSION AND LOCAL HEMORRHAGE

In a consideration of vascular emergencies, other than volume loss of blood, attention is directed to regional changes in circulation and structure of the vascular system. The flow of blood to any part depends chiefly on the normality of the local vessels, nevertheless, it is also influenced by the competence of the general circulation, the sympathetic nervous system, and the element of individual reaction. Conditions which threaten the competence of the local vessels do so either by obstructing the normal flow of blood (thrombosis, embolism and vasospasm), or by creating a rupture of the vessel with resultant hemorrhage into the tissues. Frequently one or all of these mechanisms may operate at the same time, or in sequence. For example, an embolus may lodge, induce hemorrhage, stimulate vasospasm, and, in the resulting stasis of blood, initiate thrombus formation.

Local hemorrhage occurs from trauma, or from weakening of the vascular wall usually by arteriosclerosis, syphilis, or aneurysm. Certain blood dyscrasias such as leukemia, polycythemia vera, hemophilia, purpura, and in certain instances the metabolic and infectious diseases encourage the onset, and aggravate the course of hemorrhage.

Thrombosis in a vein is usually the result of circulatory stasis. This is associated with prolonged inactivity, local injury to the vessel by trauma or infection, or changes in the blood constituents favoring coagulation. Arterial thrombosis is most frequently initiated by the presence of arteriosclerosis, infection, or aneurysm.

Embolism occurs when a section of a thrombus in either a vein, artery, or the heart loosens and is carried away in the blood current, lodging elsewhere. It may be sterile or carry the organisms of infection. For example, in endocarditis the causative

organism may be carried to the point of embolization. Air or fat emboli entering the blood stream following widespread trauma or operative procedures are occasionally encountered.

Vasospasm, or prolonged vasoconstriction, may result from cooling, from the action of certain drugs or endocrine substances, from the irritation of sympathetic nerves, and from factors not clearly defined at present. The example of vasospasm in an arm resulting from the pressure of a cervical rib is well known. The occurrence of cerebral vasospasm is questioned by some authorities. Supposedly it occurs in association with embolism and thrombosis, or, in an isolated manifestation with hypertension. In the latter case the degree of hypertension may not parallel the degree and persistence of vasospasm.

PERIPHERAL ARTERIAL OCCLUSION

Symptoms and Signs—Occlusion of an artery in an extremity is usually characterized by the sudden onset of pain, and by the absence of pulsations distal, and often for some distance proximal to the point of occlusion, the latter due to vasospasm. There is pallor and coolness of the cutaneous surface. Weakness of the extremity approaching paralysis may occur. Numbness or paresthesias are frequent. The veins tend to remain collapsed. Blanching of the skin created by pressure or by elevating the extremity remains for a long period following release of pressure or lowering of the limb. In obstruction of the large vessels, the syndrome of shock may be pronounced, this is particularly true where embolism has occurred. Where occlusion has developed gradually, as in many instances of thrombosis, pain may be absent or mild, but the evidence of reduced arterial circulation will be present.

Diagnosis—Although simple arterial occlusion should not be confused with venous occlusion, in view of their differential aspects, difficulty arises when phlebitis induces an associated arterial spasm, obscuring the palpable arterial pulse. This is usually a temporary phenomenon. Where necessary, oscillographic determinations will reveal pulsation when they are so feeble as to escape palpation. Short of surgery such a patient should be treated for the more serious arterial occlusion until vasospasm is relieved.

Treatment

The patient suffering acute occlusion of an artery should be immediately placed in bed. The extremity should be kept level with, or slightly below, that of the patient's heart. The entire body should be kept warm to encourage reflex vasodilation, but excessive heat should not be applied directly to the involved limb. If a covered cradle equipped with electric light bulb is placed over the limb, the circulating air within should not exceed 38°C (100.4°F). To apply excessive heat directly to tissue in which the blood supply is limited is to invite further injury.

In the recent literature there have appeared descriptions of a method for controlled refrigeration of an extremity involved in arterial occlusion. Although some promising results have been recorded, it would not seem advisable to recommend such procedure at the present time for use outside the facilities of a hospital.

Certain drugs may cause vasodilation and should be tried. Papaverine hydrochloride may be given intravenously in amounts from $\frac{1}{4}$ grain (0.016 gm) to $\frac{1}{2}$ grain (0.03 gm), or in double these amounts subcutaneously or orally. The medication may be repeated every three to six hours. The brief effect obtained upon inhaling ampules of amyl nitrite, or upon the sublingual administration of nitroglycerin, $\frac{1}{100}$ grain (0.6 mg), makes their use of questionable value. They may well be tried at the outset of treatment, particularly in the instance of embolism. The oral administration of methyl- β -acetylcholine in dosages of from $\frac{1}{4}$ to 1 grain (0.016 to 0.06 gm) repeated when necessary, has been recommended. Should severe side reactions be encountered with this drug, these may be terminated by the administration of atropine. Ethyl alcohol in doses from $\frac{1}{2}$ to 1 ounce (15 to 30 cc) mixed with fruit juices every four to six hours acts frequently as an excellent and prolonged vasodilator and sedative.

The employment of heparin in most cases should be carried out only in a hospital with full laboratory facilities. A thorough appreciation of the contraindications involved in the use of this drug is essential. A fatality from the induced prolongation of clotting time may result.

Since much can be done by embolectomy toward saving an

endangered extremity in embolism, recourse to consultation with a surgeon should not be delayed. Certainly, in the case of embolism, if no improvement is noted within four to six hours, surgical removal of the clot should be considered. It is stated that embolectomy is not successful after twelve hours.

For the purpose of securing vasodilation in a lower extremity an operation which may be considered is that of sympathectomy, or the injection of the appropriate sympathetic ganglia. A brachial plexus block may be used where an upper extremity is involved.

When gangrene has occurred, decision for operative procedures is primarily surgical. In elderly, arteriosclerotic, or diabetic patients, particularly in those who manifest severe toxicity, there is much to say for the recently proposed tourniquet and refrigeration anesthesia.

PERIPHERAL VENOUS THROMBOSIS

Symptoms and Signs—The clinical picture of venous occlusion varies not only with the size and position of the vessel involved, but with the presence or absence of inflammation. Pain is an outstanding symptom where inflammation, particularly periphlebitis, is severe. The absence of pain in venous thrombosis of the noninflammatory type may mask the involvement of even so large a vessel as the femoral vein. The first warning in these cases may be the occurrence of pulmonary embolism, or the complaint of edema of which the patient becomes aware after leaving bed for the first time.

In acute thrombophlebitis, symptoms are frequently rapid in onset. Where a large vessel is involved there is usually severe pain in the extremity, with acute tenderness over the course of the involved vein. The patient objects to passive movement of the limb. Edema and cyanosis are variable in degree, but when present are characteristic. Mild fever, leukocytosis, and an elevated pulse rate may or may not be present.

Diagnosis.—In instances of thrombosis in the small veins of the lower leg, dorsiflexion of the foot and kneading of the calf muscles frequently elicit tenderness when other evidence of involvement is lacking. Palpation along the large venous trunks will elicit pain. There should be little confusion between the symptoms and signs of venous thrombosis and those of arterial

occlusion When thrombophlebitis of a large vessel in its early stage is accompanied by arterial spasm, diagnosis may be difficult The procedure to be followed has been outlined under the discussion of Peripheral Arterial Occlusion

Treatment

The objects of therapy in venous thrombosis are to prevent detachment of the clot, to relieve the patient of discomfort, and to reduce or prevent edema of the involved extremity In rare instances, where there is good reason to suppose that bacterial invasion has occurred, the trial of a sulfonamide drug is probably justified, but when the invading organism is not susceptible to this drug, its continued employment may be harmful

The patient should be kept at rest with the extremity sufficiently elevated to prevent edema An anodyne such as acetyl salicylate orally in doses of 5 to 10 grains (0.03 to 0.06 gm) may be given Occasionally the use of morphine may be necessary

The use of vasodilating drugs was discussed in connection with arterial occlusion and they may be used similarly to counteract spasm in venous thrombosis Both in arterial and venous occlusion, the application of excessive heat is to be avoided The use of warm, wet packs in the treatment of thrombophlebitis has been accepted by many physicians, but care should be exercised to avoid a temperature higher than 38° C (100.4° F) Warming the body, and not the involved limb, is the safest method of obtaining vasodilation.

In many cases the angiospasm and accompanying pain in thrombophlebitis may be relieved by the surgical procedure of injecting the appropriate sympathetic ganglia Where thrombosis of a large vein, usually the femoral, is evident, certain surgeons advocate that the vein be opened and the thrombus sucked out Another procedure is the ligation of the vein proximal to the thrombus Decision in such cases will rest with the surgeon The use of heparin for thrombophlebitis, though a routine procedure in some hospitals, can hardly be recommended for use where full laboratory facilities are unavailable

The patient with venous thrombosis should be kept in bed and under treatment until tenderness has disappeared and the pulse rate and temperature have remained normal for several

days Movement of the extremity should be reinstated gradually. If edema occurs when the leg is dependent, an elastic bandage should be worn while the patient is up, and removed when he is recumbent At night the involved extremity may be elevated

PULMONARY EMBOLISM AND THROMBOSIS

The position of the lung in the vascular circuit renders it extremely vulnerable to embolism Any embolus originating within the major venous system, from the right chamber of the heart or pulmonary artery, has free access to the lung Fortunately, the structure of this organ is such that it may function adequately, despite widespread vascular occlusion Severity of reaction depends upon the size of the occluded vessel, and the competence of the collateral circulation derived from the bronchial arteries For example, pulmonary congestion due to heart failure renders the lung abnormally sensitive to vascular occlusion, and, to the degree of vascular stasis, favors thrombosis.

Symptoms and Signs—Typically, the initial evidence of an embolus is sudden pain, tightening or oppression in the thorax, often located beneath the sternum Anxiety is pronounced Pallor, frank cyanosis and dyspnea follow The skin becomes moist and cold The pulse is rapid, thready, or imperceptible. The blood pressure falls rapidly In severe embolism the clinical picture is chiefly that of shock Almost invariably, the complete obstruction of the main stem of the pulmonary artery results in death

If the patient survives the initial stage of shock, or if it is not severe, evidence of the pulmonary involvement may be more prominent The pain may be pleuritic in nature and source. It may be located along the lateral thoracic wall, aggravated by inspiration and accompanied by a friction rub Cough may be annoying Bloody or blood-streaked sputum is a characteristic but not constant finding Its appearance is frequently late

Occasionally an area of dullness may be demonstrated on percussion Moist rales are sometimes audible Often evidence of consolidation, both by physical diagnosis and roentgenographic study, is not present for hours or several days after vascular occlusion has occurred A murmur or thrill over the second costal interspace to the left of the sternum may occasionally be

detected There may be demonstrable dilation of the right ventricle

Diagnosis—The advantage of knowing of an antecedent condition within the patient which could result in embolism cannot be overemphasized The finding of such conditions (e.g., thrombophlebitis) after pulmonary embolism has occurred is of similar assistance Former mild pulmonary complaints accompanying lesser embolic episodes, which escaped diagnosis, will be recalled to great advantage at the advent of major pulmonary infarction Occlusions of small vessels in the lung are most frequently not diagnosed Pulmonary infarction may be misinterpreted as early lobar pneumonia or coronary occlusion The absence of a sufficiently elevated temperature, and the absence of pneumococci in the sputum will aid in the differentiation of the former Resort to repeated electrocardiographic studies to differentiate coronary occlusion may be necessary Certain changes in the electrocardiograph are indicative of pulmonary embolism

Treatment

The object of conservative therapy is to allay distress and restlessness The patient should be kept quiet in bed, with the head and shoulders elevated Sedation is essential Morphine sulfate in doses up to $\frac{1}{4}$ grain (0.016 gm), repeated as frequently as is necessary, is the drug of choice The use of papaverine hydrochloride in the manner discussed under treatment of vascular occlusion has been recommended Oxygen is indicated, and is administered best in the tent, but the use of a nasal catheter or mask may be necessary Since pulmonary congestion and the danger of shock coexist, the letting of blood is contraindicated Where an operating team is available to perform immediate embolectomy, this procedure may be considered in certain instances.

For pain of pleuritic type, particularly when it is located over the lower thorax, a scultetus or simple binder may bring relief, without the added discomfort of adhesive straps

The use of heparin to prolong coagulation time is advocated by some authorities Such treatment is prolonged over several days and carries an element of risk An initial intravenous dose of heparin may be given, prolonging coagulation time until the

patient can be transported to a hospital where heparinization is to be continued. The indications for use of heparin are sufficiently controversial to preclude a discussion here. The delayed effects of the drug, dicoumarin, do not recommend it for emergency use.

MESENTERIC VASCULAR OCCLUSION

The occlusion of a vein or artery in the mesentery results in infarction with necrosis of the intestinal wall. The condition is an emergency of utmost importance since early diagnosis and surgical intervention may mean recovery from an otherwise almost universally fatal condition. Thrombosis in a vessel is usually the result of inflammation transmitted from a neighboring structure.

Symptoms and Signs—The patient complains of acute abdominal pain. Early, this may be located in the upper abdomen. Frequently it is generalized. Nausea and vomiting occur. As infarction advances, the abdomen becomes distended. Early forceful peristalsis may subside and paralytic ileus becomes evident. The abdominal pain characteristically becomes less severe and constant, and mild spasmodic pain takes its place. Diarrhea and bloody stools are the characteristic but late manifestations. A rapid pulse, leukocytosis, fever, and malaise occur as the condition progresses. Peritonitis is the usual complication. Shock may be profound in massive involvement.

Diagnosis—The sequence of abrupt onset, generalized abdominal pain, and bloody stools is characteristic. When an antecedent predisposing factor to embolism (e.g., rheumatic heart disease) or to thrombosis (e.g., recent abdominal surgery) is not apparent, it may be impossible to differentiate mesenteric infarction from other so-called acute intra-abdominal conditions. Surgical exploration may be necessary to reveal the diagnosis.

Treatment—Treatment is surgical. The adjunctive use of heparin should be considered.

MISCELLANEOUS VASCULAR OCCLUSIONS AND INFARCTIONS

Occlusion of the *central artery of the retina* is infrequent. In the characteristic case there is sudden and complete blindness in the involved eye. Pain is absent or minimal. On ophthalmoscopic examination the characteristic picture of a cherry-red spot at the fovea with peripheral blanching is observed.

Delay in treatment may well result in permanent blindness. The physician should resort to the immediate use of vasodilating drugs. An ampule of amyl nitrite by inhalation affords rapid but brief effect. Nitroglycerin in the dose of $\frac{1}{100}$ grain (0.6 mg) may be given sublingually, but should be followed by the longer-acting vasodilators, which have been previously discussed. Gentle massage of the eyeball has been recommended. One of the earliest recommended uses of heparin was in this condition.

The spleen is frequently the site of infarction, but in many instances the occurrence is asymptomatic, or masked by vascular occlusion elsewhere, such as in the lungs. The chief symptom is local pain, which is occasionally severe. Where perisplenitis occurs, tenderness on inspiration or a friction rub may be detected over the organ. The spleen may be slightly enlarged. Very infrequently the lodgment of an infected embolus will result in splenic abscess, in which case continued fever and chills are indicative.

The kidney is frequently subject to infarction. Gross or microscopic hematuria may be the only indication of such happening, or there may be no hematuria. In severe involvement, pain and tenderness may be present in the costovertebral angle, flank, and lateral abdomen. Treatment is symptomatic and directed to the source of embolism.

The adrenal gland particularly in the newborn, or during meningococcic meningitis, is subject to internal hemorrhage. The signs and symptoms closely parallel those of Addisonian crisis, and treatment of both conditions is similar.

CEREBROVASCULAR ACCIDENTS

Vascular occlusion and hemorrhage within the brain are intimately associated with the complex anatomy and function of this organ. Even a brief discussion of all areas which may be involved, is not practical in the space allotted. There is, however, a similarity in the clinical pictures of most so-called cerebrovascular accidents, and the treatment directed toward the cerebral involvement in most instances will not vary. Usually the etiologic factor arises in a generalized diseased process (e.g., hypertension) or in the diseased process of a remote organ (e.g., endocarditis). Effective action is determined chiefly by consideration of these causes.

Certain disease conditions which have much in common will be considered together. Of the many cerebrovascular diseases which are clinically dissimilar, only those which are common, and those which may require treatment as an emergency will be discussed. The accompanying tabulation is offered in an at-

TABULATION

DIFFERENTIAL DIAGNOSIS IN CEREBROVASCULAR ACCIDENTS

	Hemorrhage	Thrombosis	Embolism	Subarachnoid Hemorrhage
Age	40-50	50 (and over)	10-40	20-40
Onset	Sudden	Gradual	Sudden	Often gradual
Blood pressure	Elevated	Normal	Normal	Normal or elevated
Spinal fluid	Clear or blood tinged	Clear	Clear	Bloody
Eyegrounds	Papilledema Hypertensive changes Arteriosclerotic changes	Arteriosclerotic changes	Normal, or embolic phenomena	Normal Hypertensive changes Papilledema

Note. The differential points indicated above are only generally applicable, and wide variation is often encountered.

tempt to bring out certain differential points, which are only generally applicable.

CEREBRAL HEMORRHAGE, THROMBOSIS AND EMBOLISM

Symptoms and Signs.—Frequently the initial evidence of critical cerebrovascular accident is sudden loss of consciousness. This may have been preceded for minutes or days by variable headache, dizziness, generalized weakness, a sense of pressure in the head, anxiety, or speech disturbances. In many cases, by the time the patient is found or the physician is called, coma or stupor exists.

Characteristically, the face is flushed, the limbs relaxed, the pulse bounding, and the respirations stertorous. The patient may exhibit convulsions of the whole body, or only of one or more limbs. Incontinence of urine and feces is frequent. When stupor exists, the patient may respond in a drunken manner.

Examination frequently reveals absence of the corneal, abdominal and plantar reflexes. The eyes may fix to one side. The pupils are sometimes dilated or unequal, but may be normal, or

constricted. The chief clue to diagnosis rests in demonstrating a hemiplegia involving the face, tongue, or extremities. The fact that unilateral weakness and paralysis is seldom realized early by the patient, emphasizes the necessity for a detailed physical examination. Paralysis in the early comatose stages is usually of the flaccid type. With recovery of consciousness, there is a gradual change to spastic paralysis. Correspondingly the tendon reflexes, which are usually diminished or absent during coma, become hyperactive as the patient recovers.

Diagnosis—In typical cases of cerebrovascular accident the history of antecedent disease, such as hypertension, or a valvular heart lesion, coupled with the mode of onset and the finding of unilateral central nervous involvement make the diagnosis fairly easy. In obscure instances, differentiation will usually depend on defining the cause of coma.

The so-called "uremic coma" may be clinically indistinguishable from cerebrovascular accident without resort to determination of nitrogenous retention in the blood. Hypertensive encephalopathy is usually accompanied by high blood pressure, characteristic arteriolar changes in the retina, and cupping of the disk. It may or may not be associated with nitrogenous retention. The urinous odor of the breath and changes in the eyegrounds are helpful.

The coma of diabetic acidosis may be differentiated by finding low values for the carbon dioxide combining power of the blood, large amounts of sugar and acetone in the urine, and high values for the level of the blood sugar. However, it should be emphasized that an elevated blood sugar (rarely above 200 mg per 100 cc) with glycosuria, frequently occurs in cerebrovascular accident. In diabetic coma the cherry-red color of the lips and fruity (acetone) odor of the breath may be helpful.

Epilepsy, in view of the brief and intermittent episodes, should occasion little confusion. Hysteria presents features of its own, and is not accompanied by impaired corneal, abdominal and plantar reflexes. Drug poisoning and alcoholism may be difficult to exclude. Here again, the antecedent history, and absence of unilateral central nervous involvement will be helpful. Obviously, an alcoholic odor to the breath does not exclude the presence of a cerebrovascular accident.

Lumbar puncture for diagnosis is frequently justified. Usually

no more than a few cubic centimeters of fluid should be removed. Reference to the table on page 1554 may be of aid in interpreting the findings.

Treatment

The patient with mild or severe manifestations of cerebrovascular accident should be placed in bed in quiet surroundings. The head should be elevated and turned to one side to facilitate breathing. Sedatives, other than the opiates, may be necessary to allay restlessness. The use of sodium bromide, and paraldehyde by mouth or rectum, or the use of sodium phenobarbital subcutaneously is satisfactory. Whether the patient eats, drinks, or moves his bowels is of little importance during the first twenty-four or forty-eight hours. Certainly food or drink should not be given beyond the patient's ability to accept it easily. Traditionally, a saline cathartic is recommended, but excessive purgation is ill advised. Where fluid is not taken for twenty-four hours, 1000 to 2000 cc of normal salt solution may be administered by vein or by hypodermoclysis. Where paralysis of the pharyngeal muscles persists beyond the first two or three days, feedings through a small stomach tube may be started.

The intravenous administration of solutions of *d*-glucose in the amounts of 50 cc of the 50 per cent, or 250 cc of the 20 per cent solution in an effort to relieve intracerebral pressure is of questionable value. In severe cases relief frequently follows, however, certain authorities believe that the final effect may be detrimental or at least inconsequential. Large amounts of glucose, unless saline is supplied parenterally, will dehydrate the patient whose intake by mouth is inadequate. The repetition of glucose administration should depend on the status and reaction of the patient. Drainage of the spinal fluid, gradually dropping an elevated pressure one half the distance to the arbitrary figure of normal (120 mm of water), will frequently relieve the increased intracerebral pressure. Here again there is disagreement as to the indications and final effect of such treatment. It would seem conservative to rely on the condition and response of the individual patient. In cerebral thrombosis, aspiration of spinal fluid is not indicated, and a fall in spinal fluid pressure may augment thrombosis.

Surgical intervention is not indicated except in the rare in-

stances of well localized hemorrhage. Decision usually depends on evidence of epidural or subdural bleeding.

EPIDURAL AND SUBDURAL HEMORRHAGE

Signs and Symptoms—The classical picture occurs when a patient is knocked unconscious, recovers and remains symptom free (lucid interval) for a period of from several hours to several days and then gradually develops coma and progressive hemiplegia. Whether there is a "lucid interval" or not, the gradual progression of coma and nervous involvement is characteristic. Typically, the pupil on the involved side is enlarged. Paralysis of the body is, of course, contralateral. Clear spinal fluid is the rule in epidural hemorrhage, but bloody spinal fluid accompanies subdural hemorrhage.

Treatment—While the patient is under observation and before surgical intervention is instituted, the principles of treatment in the preceding section on cerebrovascular accidents should be adhered to. Sedation is often best avoided due to danger of obscuring important diagnostic evidence. When epidural or subdural hemorrhage is suspected, consultation with a neurosurgeon is indicated.

SUBARACHNOID HEMORRHAGE

In some instances subarachnoid bleeding has been described as spontaneous. Frequently, however, the causes of hemorrhage previously discussed are demonstrable. Congenital vascular defect and aneurysm may account for the frequency of this lesion in the younger age group. Undoubtedly, many cases are mild and escape recognition.

Signs and Symptoms—The patient may experience warnings such as dizziness, headache, or stiffness of the neck. Often, as in other cerebrovascular accidents, the onset is sudden, with loss of consciousness. Characteristically, the signs of meningeal irritation are present, for example, nuchal rigidity and positive Kernig's sign. These signs may not be manifest until the patient reacts from coma. Severe headache is common. Elevated temperature, rarely exceeding 102°F (38.9°C) is frequent, except in the initial stage of massive hemorrhage when subnormal temperature is the rule. Diagnosis is facilitated by the finding of a large amount of blood in the spinal fluid. This finding will

usually serve to differentiate subarachnoid hemorrhage from the other intracerebral accidents. A smear and culture of the spinal fluid will exclude meningitis when the presence of fever suggests this disease.

Treatment—The general measures are identical with those discussed under treatment of cerebrovascular accident. Spinal puncture is often of great aid in relieving severe headache and agitation. It should be performed as the need arises in the patient's status, and not on any routine schedule. The precautions for spinal puncture have been discussed under treatment in cerebrovascular accidents. Bed rest should be prolonged until the spinal fluid is clear and colorless. Prognosis as to recurrence should be guarded.

RENAL EMERGENCIES

BOLAND HUGHES M.D.*

UNDER the term "renal emergencies" I shall consider not only some of the disease processes which affect the renal parenchyma itself, such as nephritis and pyelonephritis, but also acute urinary retention, anuria, urinary infections, urinary sulfonamide concretions, renal colic and hematuria. Any obstruction to the transportation of urine from the kidney to the bladder or from the bladder through the urethra may result in renal death just as certainly as primary renal parenchymal insufficiency. Hematuria should be considered a renal emergency because of the grave clinical implications attached to this symptom.

PYELONEPHRITIS

Pyelonephritis is the most common disease of the kidney. All bacterial infections of the renal parenchyma and pelvis, excluding tuberculosis, are included under the general heading of "pyelonephritis."

Pathology

Weiss and Parker¹ have classified pyelonephritis into four groups according to its various stages: (1) acute pyelonephritis ("pyelitis"), (2) active chronic pyelonephritis, (3) healed diffuse pyelonephritis and (4) healed pyelonephritis with recurrence. It is questionable, however, whether pyelonephritis ever "heals," because even when the infection is quiescent, fibrotic contracture may be progressively destroying kidney function.

Acute pyelonephritis is not often observed pathologically, since nearly all patients recover. The pathological picture of active chronic pyelonephritis is that of chronic interstitial inflammation with atrophy of the tubules. The process may extend to the glomeruli causing fibrosis of the capsule and glo-

* Associate in Urology, School of Medicine, University of Pennsylvania, Chief of Clinic, Urological Service, Hospital of the University of Pennsylvania.

merular tuft and thickening of the basement membrane Arterio-
lar fibrosis also occurs The entire kidney may become a mass
of scar tissue This process may, of course, be unilateral or
bilateral.

"Healed" diffuse pyelonephritis means that the patient is in
a noninfectious stage In "healed" pyelonephritis with recur-
rence, an active infection recurs and is superimposed upon a
previous stage of the disease

The usual picture of "active chronic pyelonephritis" is that
of partial obstruction of the urinary tract and an infection with
organisms of low virulence If the infecting organisms become
highly virulent, the pathological picture, of course, changes and
cortical abscesses may occur If the urinary tract obstruction
becomes too great, with the infecting bacteria remaining low in
virulence, pyonephrosis frequently results

Clinical Significance of Chronic Pyelonephritis

In a recent clinicopathological study² of sixty-two cases of
uremia, on which necropsies were performed, chronic pyelo-
nephritis was found to be responsible for the uremia in twenty-
two cases In only three of these cases, however, had the diag-
nosis been correctly made Lisa, Solomon and Gordon point out
in this study that of all the types of renal disease which may
result in uremia, pyelonephritis offers the best prognosis if diag-
nosed early and if the proper therapy be instituted Every at-
tempt must be made to eradicate the kidney infection in the
early stages of the disease

Pyelonephritis has also a direct relationship to hypertension.
Weiss and Parker¹ have estimated that in about one-half of all
patients who die of hypertension, pyelonephritic changes are
found in the kidneys and that *pyelonephritis alone is responsible
for about 20 per cent of all cases of malignant hypertension*

Clinical Picture of Chronic Pyelonephritis

Initial Symptoms—In a series of 172 cases of chronic pye-
lonephritis reported by Nesbit and Conger,³ 61 per cent had
cystitis as the initial symptom and, of these, almost one-half had
accompanying flank pain, either unilateral or bilateral Costo-
vertebral pain alone was present in 17 per cent at the onset,
sepsis alone in 4.6 per cent In this series, the symptoms existed

from three months to twenty years before pyelonephritis was diagnosed

Infecting Organisms—The colon bacillus is the most frequent invader in chronic pyelonephritis but any or many of a great variety of bacteria may be found

Roentgenographic Changes—The characteristic x-ray changes in the renal pelvis are due to the contractions of the inflammatory scar tissue and, therefore, occur only late in the disease and are definite evidence of irreversible kidney damage. The ureter may be irregularly dilated due to chronic inflammatory change

In the early stages of chronic pyelonephritis no morphological changes can be visualized by either intravenous urography or retrograde pyelography

Renal Function—In the very early stages of chronic pyelonephritis, none of the renal functional tests are sensitive enough to detect any impairment. As the disease progresses, renal function is definitely impaired, however. *The various functional studies provide the most accurate prognostic index*

Treatment

All infections of the urinary tract are secondary to infections elsewhere in the body. The first axiom of treatment is, therefore, *to eradicate all foci of infection*. The second axiom is *to correct all urinary stasis which may be present*. Complete urological examination is, of course, necessary to determine whether urinary stasis is a factor. The third axiom is *to culture the urine or do a Gram stain on the sediment, to determine the type of infecting organism*. This guides one to more intelligent urinary chemotherapy. At the present time the best drugs for the treatment of urinary infection are mandelic acid and the sulfonamides

MANDELIC ACID—This is an excellent drug for colon bacillus infections and for *Streptococcus faecalis* infection. It is given in the form of ammonium or calcium mandelate. For the adult the dose is 12 gm of mandelic acid daily, for children, 1.25 gm per 10 pounds of body weight. The drug is best given in four divided doses

A urinary pH of 5 to 5.4 is essential for bactericidal activity. Though mandelic acid is excreted unchanged by the kidneys,

additional acidification by ammonium chloride is usually necessary to reach these pH levels. The usual plan is to give ammonium chloride for a day or two (2 to 3 gm daily) before administering the mandelic acid. After the mandelic acid therapy has been started, the ammonium chloride can usually be reduced to about 0.5 gm daily. *The pH of the urine should be checked daily.*

With mandelic acid therapy it is necessary to limit the fluid intake to between 1000 to 1200 cc daily in order that the necessary concentration of the drug (0.5 to 1 per cent) be reached in the urine.

If the urine cannot be sterilized in eight to ten days with this regimen, it is advisable to discontinue the drug. Sulfonamide therapy may be started or mandelic acid again administered after one week's rest.

SULFONAMIDES—Sulfathiazole and sulfadiazine are the drugs of choice.

Sulfathiazole—Sulfathiazole has bactericidal action on practically all types of organisms invading the urinary tract. It is superior, however, in its effect on the staphylococcus and Streptococcus faecalis.

Sulfadiazine—Sulfadiazine has superior bactericidal effect against the streptococcus, pneumococcus, Friedlander's bacillus and the colon bacillus group.

Dosage—An initial daily dosage of 3 to 4 gm of either sulfonamide is usually sufficient. After two to three days the amount may be reduced to 2 gm daily for a period of six to eight days. *In treating urinary infections we do not need the large amounts of sulfonamides which are necessary in systemic infections.*

If the urine is not sterilized in about ten days' time, use the other sulfonamide after a short rest period (three to four days) (or eventually try mandelic acid).

ACUTE URINARY RETENTION

Acute urinary retention may be due to (1) prostatic enlargement caused by carcinoma, adenoma, or abscess, (2) urethral stricture, (3) foreign body in the urethra, (4) neurogenic bladder dysfunction, particularly after acute cerebrospinal injury. To diagnose the cause of the retention one should palpate along

the course of the urethra to determine whether a foreign body is present. If a periurethral induration or abscess accompanies a urethral stricture, palpation of the urethra is a necessary diagnostic procedure. Rectal examination will determine the size and consistency of the prostate. A history of spinal injury or neurological disease should make one suspect the possibility of a neurogenic bladder. Neurological examination revealing any sensory or motor changes in the lower trunk or in the lower extremities should certify the diagnosis. The treatment of neurogenic bladder will be discussed later but in all other forms of urinary retention a 16 F soft rubber catheter should be gently inserted into the urethra and, if possible, into the bladder. If the catheter will not pass by an obstruction in the anterior or membranous urethra, one is very likely dealing with a urethral stricture, particularly if no foreign body has been palpated along the course of the urethra.

Treatment of Acute Retention Due to Urethral Stricture

To relieve the acute retention due to urethral stricture it is first necessary to pass a filiform through the strictured area into the bladder. *Woven Phillip's filiforms which can be threaded to a woven Phillip's urethral catheter* are preferred and are far safer than the old-fashioned whale-bone filiforms with the tunneled metal Gouley's catheter, which was threaded over the filiform. Woven Phillip's urethral catheters, threaded for the woven Phillip's filiform, should be available in sizes 8 to 28 F. After the filiform has been inserted through the strictured area into the bladder, an 8 or 10 F Phillip's catheter is threaded to the filiform and passed into the bladder to relieve the acute retention. The urethral stricture, of course, must then be subsequently dilated, preferably by again passing a Phillip's woven filiform and threading to it metal Le Fort urethral sounds (sizes 8 to 20 F). After the stricture reaches 20 F caliber, ordinary urethral sounds may then be used to dilate the stricture to the normal caliber of 32 F.

Treatment of Acute Retention Due to Prostatic Enlargement

Types of Catheters

- 1 Soft Rubber Catheters. These are the most commonly-used urethral catheters. Sizes 8 to 28 F should be available, the

8 or 10 F caliber being sufficiently small to use in a new-born male child. The Robinson catheter has two advantages over the ordinary soft rubber catheter. It has two eyes and its hollow tip permits the use of a metal stylet, the tip of which would slip out of the ordinary whistle-tip type catheter, in those rare cases of prostatic obstruction in which a semirigid rubber or a woven catheter cannot be inserted. Another advantage is that the catheter is made of latex rubber which is not as irritating to the urethra as ordinary rubber when used as an indwelling catheter.

- 2 Semirigid Rubber Catheters. These catheters are extremely practical for use in prostatic obstruction when the ordinary soft rubber catheter cannot be inserted. Sizes 12 to 24 F are advisable. The coude, olive, solid tip assists the catheter in riding over the prostatic obstruction.
- 3 Woven Catheters. These are more rigid than the rubber type and are of the greatest value in cases of prostatic obstruction. Both the ordinary coude-tip type, in sizes 6 to 30 F, and the modified natural curve, olive-tipped type, in sizes 10 to 24 F should be available.
- 4 Metal Catheters. These are used very infrequently by present-day urologists. Woven catheters have replaced the metal ones in relieving the retention of prostatic obstruction. (Owing to the great danger of urethral damage, a metal catheter should be used only by those experienced in urethral catheterization.)

Decompression of the Bladder—In any long-standing urinary retention, such as the chronic retention of prostatic obstruction or the acute retention developing from chronic prostatic retention, the bladder should be emptied gradually to prevent the fall of blood pressure and renal damage which sometimes occur if the retained urine is completely withdrawn from the bladder at the time of catheterization. In order to permit gradual adjustment of the blood pressure and bladder pressure to lower levels and to prevent renal damage from compensatory edema caused by the sudden lowering of intravesical pressure, the bladder should be gradually decompressed as follows.

The soft rubber catheter is inserted into the bladder with the end clamped to prevent the premature escape of urine. The catheter is then connected to a rubber tube about 6 feet long, which has been filled with sterile water and clamped at both

ends before being joined to the urethral catheter. This rubber tube is then connected to one of the arms of a glass Y-tube, which is inverted and fastened with adhesive either to the bed or another supporting object at such height above the distended bladder that, when all clamps are removed, a few drops of urine trickle through the inverted Y-tube when the patient takes a deep breath or voluntarily contracts his bladder. Another rubber tube is attached to the other arm of the inverted Y-tube and carries the urine to a drainage bottle. The Y-tube is gradually lowered every three to four hours as the blood pressure and bladder pressure readjust themselves.

Decompression usually takes about forty-eight hours. Bladder decompression is not necessary in postoperative urinary retention unless this is superimposed on a chronic prostatic retention.

If the bladder cannot be emptied by any of the above urethral measures, a *suprapubic cystostomy* becomes imperative. If, however, operative facilities are not available, suprapubic bladder puncture is indicated. To accomplish this a lumbar puncture needle should be inserted through the skin just above the symphysis in the midline. The needle is passed between the recti muscles and through the bladder wall. It should then be inserted about an inch and a half further into the bladder cavity so that complete emptying of the bladder will be facilitated. Bladder puncture, however, is only a temporary emergency procedure and should be followed by suprapubic cystostomy as soon as possible.

Management of the Neurogenic Bladder

Under this heading we are concerned primarily with the management of acute retention, following cerebral spinal injury. In the war of 1914 to 1918, 80 per cent of the American and English soldiers who sustained a paralytic bladder due to spinal cord injury died as a result of the bladder paralysis rather than of the spinal injury itself. *The cause of death was renal sepsis*, and this sepsis resulted from infection that was introduced into the bladder by urethral catheterization. It is therefore of paramount importance to reduce the incidence of urinary infection to an absolute minimum. A transverse lesion at any level of the cord or cauda equina usually results in three urinary phases: (1) retention, (2) incontinence of overflow, (3) automatic mic-

turition Urinary retention lasts for varying lengths of time, but gradually results in the incontinence of overflow This overflow incontinence should be prevented

To prevent renal infection and to relieve the acute retention before the incontinence of overflow occurs, the following rules should be observed

- 1 *Do not catheterize the bladder under any consideration*
- 2 *The urine should be manually expressed from the bladder every four hours* The bladder should be massaged from above downward toward the symphysis with the patient lying on his side The patient should strain to exert as much intra-abdominal pressure as possible at the time the bladder is being manually expressed *This schedule should be followed every four hours with religious punctuality* Manual expression is contraindicated only if the urine becomes infected Daily urine examinations should therefore be made
- 3 *Suprapubic cystostomy is indicated if manual expression be impractical or if urinary infection occurs* Suprapubic cystostomy reduces the hazards of ascending pyelonephritis to an absolute minimum and, of course, completely relieves the urinary retention

Acute Retention Due to Foreign Body in Urethra

Treatment depends on the nature of the foreign body and its location in the urethra If the foreign body is small and is located in the anterior urethra, one may be able to remove it by grasping the foreign body with a long forceps or clamp inserted into the urethra If the foreign body cannot be easily removed in this manner, special urological treatment is necessary

HEMATURIA

Hematuria is the outstanding symptom of urinary disease but too often its importance is underestimated by both the patient and his physician Frequently, hematuria is both painless and intermittent and it is the cessation of the bleeding which is the more dangerous factor, for this lulls the patient into a false sense of security and makes him think that he is well *As hematuria is merely a sign of existing disease, its occurrence demands immediate and thorough urological examination to determine the nature of the pathological process* When the bleeding is at the beginning of urination, the source is usually the anterior urethra,

occasionally the posterior urethra. *Terminal* hematuria usually originates in the posterior urethra or in the bladder. *Total* hematuria more often indicates that the bladder, ureter, or kidney is the seat of disease. One cannot, however, rely too much on the type and appearance of the blood.

Blood in the urine is an extremely serious symptom. MacKenzie in 1932 found that 75 per cent of the cases of hematuria were caused either by tumor, infection, calculus, or nephritis. In 96 per cent of the cases, the causative lesion was in the urinary tract and over 40 per cent of these lesions were neoplastic. In a small number of cases the cause of the hematuria is not found on the first complete urological examination (cystoscopy, estimation of the individual kidney function, examination of specimens of urine from each kidney, pyelography and intravenous urography). In eighty-nine such cases, however, as Cahill⁴ has reported, re-examination at a later date found the causative lesion in fifty-five of the cases. Thus only a very small percentage could be classified as "essential" hematurias.

The following tabulation and grouping (Cahill) can be used to classify and to guide the study of hematurias.

- I Hematuria in general diseases
 - A Acute fevers especially in the severe forms, malaria, acute articular fever, scarlet fever, tonsillitis, etc
 - B Chronic infections
 - 1 Endocarditis (renal infarction)
 - 2 Purpura
 - 3 Syphilis
 - C Diseases of unknown etiology
 - 1 Hodgkin's disease
 - 2 Leukemias
 - 3 Periarteritis nodosa
 - D Vitamin deficiencies
 - 1 Scurvy
 - 2 Liver deficiencies
 - E Inborn anomalies
 - 1 Hemophilia
- II Hematuria from causes within the urinary tract
 - A Renal causes
 - 1 Congenital anomalies (polycystic disease)
 - 2 Injuries

- 3 Motility
- 4 Calculi or crystals
- 5 Infections
 - (a) Acute pyelitis, pyelonephritis
 - (b) Chronic pyelonephritis, nephrosis
 - (c) Specific tuberculosis
- 6 Nephritis
- 7 Parasitic diseases as filariasis
- 8 Tumors capsular, parenchymal, pelvic
- 9 Drugs turpentine, phenol, cantharides, methenamine, salicylates, sulfonal, barbiturates, organic acids as mandelic, sulfanilamide and other derivatives
- 10 Local vascular changes
- 11 Unknown origin
- B Ureteral causes
 - 1 Trauma
 - 2 Calculi
 - 3 Infection, ureteritis cystica, stricture
 - 4 Tumors
- C Vesical causes
 - 1 Malformation
 - 2 Trauma
 - 3 Calculus or foreign body
 - 4 Infections, including prostatic or urachal
 - 5 Parasitic as bilharziasis
 - 6 Tumors
 - 7 Epithelial changes as leukoplakia
- D Urethral causes
 - 1 Malformations
 - 2 Injuries
 - 3 Calculus or foreign body
 - 4 Infections
 - (a) Acute urethritis, chancre, chancroid
 - (b) Chronic urethritis, stricture
 - 5 Tumor
 - 6 Nevus
- III Hematuria from diseases invading the urinary tract
 - 1 Acute appendicitis
 - 2 Acute or chronic salpingitis
 - 3 Acute or chronic diverticulitis of the colon
 - 4 Intestinal or female genital tuberculosis
 - 5 Abdominal or pelvic tumors
 - 6 Extrarenal or extra-ureteral tumors

- 7 Perforations of gastric or duodenal ulcers
- 8 Perforations of aneurysms
- 9 Perforations from osteomyelitis

RENAL COLIC

Any sudden blockage in the transportation of urine from the renal pelvis to the bladder may cause renal or ureteral colic. The most frequent cause of renal colic is sudden blockage at the pelvo-ureteral junction by a renal stone or sudden ureteral blockage by a small stone which has passed from the renal pelvis to lodge in the ureter. Renal colic may also occur when the ureter becomes acutely kinked due to a ptosed kidney. In a typical attack of renal colic, severe, intermittent, lancinating pain radiates from the lumbar region along the course of the ureter to the genitalia.

Diagnosis

A typical attack of renal colic can be readily diagnosed from the history and physical examination but this diagnosis *must be substantiated* by finding a *urinary obstruction* either by x-ray (to detect opaque stones) or by ureteral catheter (nonopaque stones) or by relieving the colic, when due to ptosed kidney, by placing the patient in the knee-chest position. Further confirmation of the diagnosis is the *presence of hematuria* (also from a ptosed kidney). Thorough urological survey will, of course, reveal the complete diagnosis and this should be done as soon as possible.

Treatment of Renal Colic

- 1 *Do not rely on morphine to relieve pain*
- 2 Administer papaverine hydrochloride hypodermically (0.03 gm) *to relieve spasm which is causing the pain*. Repeat dosage every half hour for three or more doses if necessary.
- 3 Place patient in a very hot bath. This sometimes completely relieves the colic.
- 4 Place patient in knee-chest position if "Dietl's crisis" from a ptosed kidney is suspected.
- 5 Insert a ureteral catheter to the renal pelvis *to relieve the obstruction*. Allow catheter to indwell.

- 6 If none of the above measures are effective, give the patient spinal anesthesia or intravenous anesthesia (sodium pentothal) for a short time
- 7 After complete urological examination determines the nature and location of the obstructive uropathy, surgical or instrumental means must be employed to correct the cause of the renal colic

URINARY SULFONAMIDE CONCRETIONS

Formation of and deposition of sulfonamide crystals in the renal tubules, renal pelvis and ureter may produce very serious urinary obstruction and result fatally. This is more likely to occur when the sulfonamides are used in large doses to treat severe systemic infections than in the treatment of urinary infections and is particularly prone to occur when the fluid intake, and thus the *urinary output*, is low. With a low urinary output the concentration of sulfonamide in the urine is greatly increased and precipitation of the crystals (particularly the acetyl form) is favored. Complete anuria may result when both ureters, or the tubules of both kidneys, are blocked.

Prevention

1 *Never let the urinary output fall below 1500 cc daily* when large doses are being used to treat systemic infections. If the output of urine falls below this level, stop the drug temporarily until the urine volume is increased.

2 *Administer alkalis* during the sulfonamide therapy to raise the urinary pH and thus increase the solubility of the drug in the urine. Sulfonamide solubility in urine is minimal from pH 5.6 to 6.6, is doubled or tripled at pH 7.5 and increased tenfold at pH 8.0. *Give sufficient sodium bicarbonate by mouth to keep the urinary pH at least at 7.5.* A constant check on the urinary pH (nitrazine paper) is necessary.

Treatment

1 *The occurrence of hematuria or lumbar pain* during sulfonamide therapy indicates the probability of sulfonamide concretions being present somewhere in the urinary tract. Sulfonamide concretions are nonopaque to x-ray.

2. *Stop the drug immediately*

3 *Increase the fluid intake and alkali administration*

4 *Catheterize one or both ureters to establish drainage from the renal pelvis* Catheters are allowed to indwell and the renal pelvis or pelves are irrigated with sterile physiological saline solution

This procedure will not, of course, relieve the urinary obstruction from *tubular blockage*

5 If catheters cannot be passed into the renal pelves, nephrostomy may be necessary if anuria is complete

ACUTE NEPHRITIS

Acute nephritis may develop suddenly, presenting all the classic textbook features of the disease, such as hypertension, edema, pyrexia and hematuria, or it may be insidious in its onset, entirely escaping diagnosis unless the evidence of renal involvement is found on urine examinations

In making the diagnosis of acute nephritis, it must be remembered that, whereas hypertension, edema, nitrogen retention, uremia and convulsions are the main syndromes found in the acute stage, *abnormalities of the urine may be the only constant feature present* On the other hand, in the more severe forms of the acute disease, one must look for and be prepared to treat such complications as hypertensive encephalopathy and cardiac decompensation McIntosh⁵ stresses the fact that a mild circulatory failure occurs more frequently than is realized in patients with nephritis and that care must be taken to spare the heart. The prognosis is proportional to the degree of circulatory failure

Treatment

Treatment of the acute form of nephritis must be largely symptomatic and is not standardized In general, psychic and somatic rest is necessary, hypertension should be controlled by magnesium sulfate, morphine may be needed, oxygen promotes the patient's comfort and aids in supporting the circulation, and digitalis may be of value if used with care. In more detail, the treatment should consist of (1) complete bed rest until hematuria, edema and albuminuria have disappeared, (2) dietary measures—restriction of protein and exclusion of fats in the early stages, and (3) restriction of fluids to 1500 to 2000 cc. daily

for a few weeks. One must remember that we are dealing with impaired renal function and attempts to "flush out" the kidney are futile. For convulsions, Roper⁶ recommends venesections of 10 to 15 ounces of blood supplemented by rectal infusions of 4 ounces of 50 per cent magnesium sulfate. Bromides, chloral hydrate, and sometimes morphine may be necessary. Sometimes lumbar puncture may help. Winkler, Smith and Hoff⁷ recommend slow intravenous infusion of 500 cc of 2 per cent magnesium sulfate solution for the treatment of convulsions. The injection may be repeated, but allowances should be made for decreased elimination of the drug by the diseased kidneys. Not more than $3\frac{1}{2}$ ounces (100 cc) of 2 per cent magnesium sulfate solution should be given if renal insufficiency is severe, as respiratory failure may ensue.

Williams, Longcope and Janeway⁸ recommend the use of sulfanilamide in the treatment of acute glomerulonephritis and have reported very good results with it. I feel it should be used in all acute cases and that it is the sulfonamide of choice. Only 1 to 1.5 gm should be given daily for one week.

I agree with the almost unanimously held concept that chronic glomerulonephritis is the result of the presence of more or less minimal unhealed lesions in the kidney following the acute process of the disease, and feel that the prognosis of acute nephritis is not as good as some would have us believe. The severity of the acute phase is no criterion in determining the prognosis. Murphy and Peters⁹ have very ably outlined the management of the patient after the acute stage is over, as follows: (1) At least four months of bed rest, (2) a diet consisting of 0.75 to 1 gm of protein per kilogram of body weight, (3) restriction of sodium chloride intake to 5 to 6 gm per day, (4) adequate but not excessive fluid intake, (5) vitamins, especially A, B complex, C and D, plus iron medication, and (6) removal of foci of infection about one month after the acute episode.

ANURIA

The occurrence of anuria is of very serious clinical import, and demands immediate study to determine its cause. Proper treatment can be instituted only after the cause of the anuria is known.

In a general way we may classify anuria into three different groups

1 Secretory

- (a) Prerenal, such as when the causes are proximal to the kidney (circulatory failure, diminished fluid intake, shock, hemorrhage, etc.)
- (b) Renal, due to inadequate secreting renal tissue (acute nephritis, advanced hydronephrosis, polycystic kidneys, advanced pyelonephritis, acute nephrosis, etc.)

2 Obstructive or Postrenal

(a) Intrinsic

- 1 Ureteral blockage (bilateral)
- 2 Ureteral blockage in single kidney
- 3 Lower urinary tract obstruction as by tumors of the bladder and prostate

(b) Extrinsic

- 1 Ligation of the ureters during gynecological operation
- 2 Retroperitoneal tumors and neoplasms, particularly extension of carcinoma of the cervix

3 Composite Group

- (a) Traumatic injury of kidneys and ureters
- (b) Crush injury to limbs resulting in muscle necrosis and subsequent renal failure
- (c) Extensive burns

The immediate problem in the treatment of anuria is to determine as quickly as possible the type and cause of anuria. The obstructive type of anuria lends itself more readily to treatment and it is the treatment of this type that we shall briefly consider.

Treatment of Obstructive Anuria

The diagnosis of obstructive anuria can be readily made from the history and physical examination. All our efforts should be directed toward locating and relieving the obstruction as soon as possible. The following are the steps which should be taken to accomplish this:

- 1 *Catheterize the bladder* to determine if any urine is in the bladder. (This also differentiates between acute retention and anuria.)
- 2 *Determine the presence of opaque ureteral or renal calculi* by a survey x-ray film of the urinary tract.

- 3 *Cystoscope the patient and catheterize both ureters to determine the patency of the urinary tract Leave catheters indwell after obstruction is overcome*
4. Unilateral or bilateral ureterostomy or nephrostomy is indicated if ureteral catheters do not relieve the obstruction

GASTRO INTESTINAL EMERGENCIES

GUY M. NELSON, M D *

and

JOHN H HODGES M D †

THE purpose of this article is to discuss briefly and to re-emphasize some of the ordinary problems encountered in the diagnosis and treatment of the common gastro-intestinal emergencies. Improvement in diagnostic precision follows the knowledge of the usual findings, the atypical findings, and a thoughtful consideration of the differential diagnostic possibilities. The latter will not be included here. Improvements in treatment follow early diagnosis, the prevention and restoration of disturbances in fluid, food and electrolytic changes of the body, the proper use of drugs, and operative intervention when necessary.

ACUTE PERFORATION OF PEPTIC ULCERS

Whatever the cause or causes of peptic ulcer, the incidence has risen, likewise perforation. It is amazing to note that there has been no significant improvement in the mortality rate in these cases in the past twenty years, despite the general progress in medical management of many other conditions. When one considers this, the fault appears to lie in the continued failure to make early diagnoses and to institute prompt surgical measures. In such a dramatic condition, this is a serious criticism of either our promptness or diagnostic acumen.

Diagnosis

In approximately 80 per cent of all cases, one is able to obtain a previous history of periodic pain and discomfort after eating, which was relieved by food or alkalis. It is true that in the

* Assistant Professor of Medicine, Jefferson Medical College. Assistant in Medicine, Jefferson Hospital.

† Fellow in Medicine, Jefferson Medical College.

other 20 per cent such a history may be entirely absent or too indefinite to be dependably suggestive

Pain—This dramatic episode appears suddenly, is severe and epigastric in location. It is referred in most cases either to the right, left, or both shoulder tops. It is highly important to learn of this early occurrence, because later the character of the pain and the general appearance of the patient change. At the onset the patient is still, usually is perspiring, is breathing with his chest, and is holding and protecting his abdomen, this is in contrast to the behavior of a person with colic. As time goes on, the pain becomes less severe and more diffuse, extending to those areas where the peritoneum is involved as the peritonitis spreads. In those cases where the perforation is anterior and distal to the midgastric region, the pain will extend down the right half of the abdomen, frequently confusing the picture with that of acute appendicitis. This is the result of the material extruded flowing down the right colonic region into the pelvis. Pain extends down the left side in those cases where the perforation is anterior and proximal to the midgastric region.

When the perforated area is in the upper right abdominal quadrant, the great omentum may localize the process, but the history of this distinctive, early, sudden, severe pain precedes the less severe localized pain which follows.

Frequently the posterior perforations become localized but the history of sudden, severe pain precedes the less severe pain which follows when localization is complete. The latter is quite apt to be colicky and referred to the back. Rivers has said "When the pain of gastric ulcer shifts definitely to the left, slightly upward or to the back, when the pain of a duodenal ulcer shifts to the right, upward, over the area of the liver or through to the back, one can correctly assume deep penetration or partial perforation of the lesion."

In the diagnosis of acute perforation the most important aid is a careful history, which includes a sudden severe pain, often following the ingestion of food, changing in its character and in its distribution according to the position of the perforation. One cannot stress too much the meticulous care with which the history should be obtained and the importance of obtaining this before the picture is confused by hours of illness.

Temperature and Pulse—Early, both are apt to be depressed, later they are affected by the complicating peritonitis, diagnostically these are not important.

Tenderness and Rigidity—These findings are of equal importance with the history of pain. Boardlike rigidity has been described and is usually found. On the other hand, it may be much less than boardlike and early, may be confined chiefly to the upper abdomen or may disappear entirely just after the patient has reacted from shock. When the lesion is localized in the upper right quadrant, the findings are those of tenderness and rigidity, much as one would find in acute cholecystitis. In those cases where perforation is localized posteriorly the tenderness and rigidity are localized to the upper part of the abdomen and are less marked. In most of the anterior perforations these findings are present in the epigastrium in typical form and spread down the abdomen either to the right or left side and gradually become general, when general peritonitis has had time to develop. It is in these cases that rectal palpation is of such great value. As the peritonitis spreads, rectal tenderness is found bilaterally.

Liver Dullness—In those perforations where a sufficient amount of air is extruded, the area of liver dullness is decreased. This may be verified by x-ray studies. Its absence should not influence one's diagnosis, its presence is helpful.

Peristalsis—The abdomen is usually silent.

Leukocyte Count—Early, the polymorphonuclear cells may be normal or increased, later, as peritonitis develops, they are increased almost without exception.

Treatment

The most important acts in successful therapy are a diagnosis made before the sixth hour, the immediate entrance of the patient into a hospital and prompt surgical intervention. After the sixth hour, the mortality rate rises rapidly and there are many who feel that surgical intervention is unnecessary if delayed fifteen hours.

Morphine sulfate should be given hypodermically in sufficient amounts to relieve the patient and make him reasonably comfortable. Usually it requires $\frac{1}{2}$ grain (0.032 gm) or more.

In order that the gastric contents may be prevented from being expelled into the peritoneal cavity, immediate intubation should be performed and continuous gastric suction maintained.

It is well to place the patient on the left side in the hope that one may be able to control partially the spread of the peritonitis to the left, instead of to the hepatic region.

Plasma (if unavailable, a 5 per cent solution of acacia) is used intravenously to combat shock, and 5 per cent glucose in normal salt solution to maintain fluid balance. It is rarely necessary to administer more than 16 to 32 gm. of the former and 1000 cc. of the latter prior to operation, unless the patient is seen late in the course of the illness.

In cases where the process has extended beyond the stage of chemical peritonitis the intravenous or possibly the local use of sulfonamides is indicated.

A general survey of all the organs of the body should be made and supportive therapy used, when needed. This especially applies to the heart, lungs and kidneys.

GASTRO-INTESTINAL HEMORRHAGE

Acute gastro-intestinal hemorrhage of emergency degree may arise from many causes, the chief one of which is peptic ulcer. Other causes are esophageal varices, malignancy, diseases altering the hemostatic properties of the blood, inflammation such as acute gastritis, foreign bodies, and severe acute febrile diseases including malaria, yellow fever, and "malignant" scarlet fever.

Diagnosis

Symptoms are dependent upon the rapidity and amount of bleeding. In the adult the immediate loss of 60 cc. of blood is sufficient to cause melena, and the rapid loss of more than 300 cc. is likely to cause subjective symptoms. Hematemesis and melena are nearly always present, singly or combined, where hemorrhage is of emergency degree. Usually blood persists in the stools for days after bleeding has stopped. Usually vomiting of blood may be accepted as evidence of active bleeding. Faintness is often an early perception and may be followed by dizziness, perspiration, weakness, pallor, thirst and loss of consciousness. As bleeding continues, the patient becomes apprehensive and restless, the blood pressure falls, the pulse rate increases,

and progression to an imminent or actual shocklike state follows

Treatment

Absolute Bed Rest—This condition is terrifying and is accompanied, as a rule, by great environmental confusion. Statistical data vary considerably about its seriousness. It is our feeling that most patients, if their cases are properly supervised, survive. Often there is the harmful tendency to be too attentive, disturbing the patient's rest and causing increased anxiety, and to administer fluids and blood prior to their need. Obviously the patient should be placed in a hospital, the head lowered and the body surrounded with warm coverings.

Quiet lessens the circulatory requirements and the tendency to bleed. These patients are constantly in danger and require careful and capable nursing. In the first twenty-four hours the blood pressure and pulse should be estimated every one-half hour to one hour, thereafter according to clinical indications, sudden massive blood loss may precipitate a crisis which, if unnoticed, may be irreversible. Progressive rises in pulse, especially if it reaches 130 per minute, or a fall in blood pressure below 90 to 80 mm of mercury systolic or 50 to 40 mm diastolic, with clinical evidence of a failing circulation, warrants a consideration of the use of fluids.

Parenteral Fluids—Potentially, *whole blood* is the most important. Typing and cross-matching should be performed when a bleeding patient is first seen, regardless of the possibility of cessation of hemorrhage. No one can foretell the circulatory status of the immediate future. Three hundred to 500 cc of citrated blood may be given intravenously in one-half to one hour in the event of a rapidly falling blood pressure or increasing pulse rate. In our opinion this should not be done until there is clinical evidence of a maintained circulatory stabilization (three to five days as a rule) unless blood is required to maintain vital functions incompatible with living. With a stabilized blood pressure it may be administered with greatest value at a rate of 100 to 150 cc. an hour.

Plasma may be administered intravenously, by syringe, for incipient or actual shock. The dose is 16 gm diluted in 45 cc of sterile distilled water, injected over a period of not less than

five minutes Repeated administrations of this amount of plasma may be given every fifteen minutes to an hour as indicated clinically.

Saline solution (with or without glucose) should be started immediately, temporarily, when blood or plasma is suddenly necessitated but not yet available Parenteral saline and glucose solution may be used to replace or supplement the oral fluid intake It is unnecessary to give the saline-glucose solution (except in emergency states) until the twenty-four-hour urinary output has dropped below the 500-cc level or in case of acidosis It is advisable to administer it slowly in 500-cc amounts every six to twelve hours, the total twenty-four-hour amount and the time-intervals for its administration depending upon the urinary findings

Intramarrow injection may be indicated where venous puncture is impossible and it is desirable to place fluid in the vascular system Up to six years of age the tibia is the ideal site for marrow injection, after six years the sternum is preferable.

Red blood cell counts and hemoglobin determinations should be done once or twice a day to aid clinical judgment as to when transfusion is indicated in the absence of shock Early in the course of this condition they are not as quickly reliable as the general clinical picture, the blood pressure and pulse, because it requires several hours for the blood to readjust itself to the hemoconcentration following blood loss When the arbitrary levels of 2,000,000 to 2,500,000 red blood cells or 35 to 50 per cent hemoglobin (5.6 to 8 gm) are reached and the circulation stabilized, slow transfusion of 500 cc of whole citrated blood (100 to 150 cc per hour) may be indicated every two or three days until the red cell blood count has reached the 4,000,000 level

Sedatives—Sedatives should always be given to the point of insuring mental and physical quietude in these cases where apprehension and restlessness so commonly occur. They must be repeated often Barbiturates, such as sodium phenobarbital in 1½- to 2-grain (0.1 to 0.13 gm) doses, if well tolerated, may be more effective than morphine sulfate (⅛ to ¼ grain [8 to 16 mg]) Experimentally, morphine tends to cause excess relaxation of the duodenal wall and probably has the same effect on other nonsphincter portions of the gastro-intestinal tract How-

ever, in actual practice, morphine remains the choice of the majority of clinicians

Fluids and Food—Most accepted methods of administration may be classified under two headings (1) starvation, (2) immediate feeding

1 STARVATION

This means a complete deprivation of food and drink usually for three to five days until hematemesis and clinical evidence of bleeding have disappeared. During this time, parenteral fluids are relied upon to maintain fluid balance and to furnish a small amount of nourishment. Sedatives are required at frequent intervals for comfort. Despite the recent trend toward immediate feeding, starvation is frequently the first choice, especially in those cases seen early following hemorrhage.

Statistical reviews would incline one toward the immediate feeding of patients with hemorrhage. When successful, this method causes the patient to lose less weight and decreases the total number of days of incapacity. On the other hand, such data can be misleading and personal experience should influence one in making a choice of methods. One of us has seen several deaths in patients who were fed promptly, as against one death in that group which were not. As a consequence we prefer initial starvation followed by one of the first two methods listed below

(a) Modified Sippy Diet (Alkalies)

Equal parts of milk and cream to make 3 ounces (90 cc) are given hourly from 7 00 A.M. to 9 00 P.M. Sodium citrate (3 to 5 gm per liter) may be added to milk in case cream is not tolerated

Calcium carbonate (2 to 4 gm [30 to 60 grains]) is given hourly with milk and cream or between the feedings in 2 to 3 ounces (60 to 90 cc) of water

The feedings combined with 4 gm (60 grains) of calcium carbonate are given every two hours during the night.

Magnesium oxide, 1 gm (15 grains), is given two to five times daily in place of the carbonate to prevent fecal impaction.

With this regimen one must watch for alkalosis. With the onset of signs, immediately stop all alkalies and increase fluid and chloride intake

(b) Andresen Gelatin-Milk Mixture

	Amount	Carbo- hydrate	Fat	Protein	Calories
Gelatin	30 gm			27	100
Glucose	60 gm	60			240
Cream (20%)	100 gm	3	18	3	180
Milk	900 gm	36	27	27	550
		<u>99</u>	<u>45</u>	<u>57</u>	<u>1070</u> approximately

Feedings after hemorrhage

- 1 No feeding during sleep
- 2 No water, ice, or other drinks
- 3 At time of serving, such flavors as chocolate, vanilla, coffee, or tea may be added

4 Serve cool or warm as follows

1st and 2nd days	4 oz q 1½ hours
3rd, 4th and 5th days	5 oz q 2 hours
6th and 7th days	5 oz q 2 hours

Now add to each of four feedings one of the following

1 soft-boiled or poached egg, 3 oz cereal, custard, jello, ice cream

8th and 9th days As above, but add two extras to each of three feedings

10th day and on
Water

Ulcer diet
Start on 5th day—
1 oz at a time
and increase
daily ½ oz
½ oz each night
starting on 2nd
night

Mineral oil

2 IMMEDIATE FEEDING METHODS

(a) Meulengracht Method Institute promptly on admission to hospital

(1) Puree diet

6 00 A.M. Tea, white bread and butter

9 00 A.M. Oatmeal with milk, white bread and butter

1 00 P.M. Dinner—meat balls, chops, vegetables, applesauce, tapioca pudding, omelet, etc

3 00 P.M. Cocoa

6 00 P.M. White bread and butter, sliced meats, cheese, etc., tea

(2) Sodium Bicarbonate,

Mag Subcarbonate

Ext Hyocyanus

1 teaspoonful t.i.d

ââ 15 gm
2 gm

(3) Lactatus ferrosi, 0.5 gm t.i.d

(b) Aluminum Hydroxide by Intubation (after Woldman)

- (1) On admission pass soft nasogastric tube to lower end of esophagus and begin drip of $33\frac{1}{3}$ per cent suspension of colloidal aluminum hydroxide at 15 drops a minute, day and night, for ten days. If the patient is unable to tolerate the tube, give 1 ounce (30 cc) every hour during the night.
- (2) Soft bland diet every two hours.
- (3) Mineral oil daily or enema every other day for constipation.

Vitamins—Vitamin K is indicated in 1- to 2-mg doses daily intramuscularly, if a deficiency exists (blood prothrombin below 50 per cent). Vitamin C is given in 300-mg doses daily, orally or intravenously, if scurvy is present (or orange juice—16 ounces).

Surgical Intervention—Exploration supported by the use of parenteral therapy during and after operation is indicated in cases of peptic ulcer with hemorrhage at any time (without delay) when transfusions fail to maintain a sufficient number of red blood cells and hemoglobin to carry on the vital functions of the body. Ligation of the bleeding vessel is necessary. The small group of bleeding ulcer cases failing to respond to medical therapy tends to be in the ages beyond forty-five years. Splenectomy is often curative and life saving in splenic anemia and thrombocytopenic purpura.

ACUTE CHOLECYSTITIS

In this discussion we are concerned only with those cases which may or can become surgical emergencies. The statistical data on this type of disease are probably very different from those which might be collected by the general practitioner. Acute cholecystitis is a more common condition than it is generally thought to be. Fully 98 per cent of the cases are associated with gallstones. The pathological picture appears to be one of obstruction, inflammation, and a mechanical disturbance of the blood supply, due either to pressure on the vessels produced by the stone, or to the resulting infiltration and edema of the gall-bladder itself, or both. Most physicians would prefer elective management of this condition, regardless of whether they favor surgical or medical procedures. We suggest that all acute proc-

esses be observed closely until the danger of gangrene, empyema and perforation has been determined. We do not subscribe to the belief that the pathological processes cannot be evaluated by the clinical picture. It is our feeling that usually the mistaken diagnoses result from a failure to make a careful and detailed study of the process as it develops. Undoubtedly in many instances this failure occurs because the physician is called late, but it should serve as a warning to us that we may not be negligent in our observations of the process as it evolves.

Diagnosis

Pain—Acute cholecystitis is ushered in by an attack of colicky pain, beginning in the epigastrium and radiating to the right hypochondrium and to the tip of the right shoulder blade. In perhaps 5 per cent of cases the pain may radiate to the right shoulder tip. Gradually the pain becomes more localized over the gallbladder region, is less severe but constant. Early, the patient is apt to be restless and to thrash about, but later he guards himself and prevents the upper abdomen from moving, even to the point that respiration is thoracic. In a very small percentage of cases the pain begins mildly, is more of a discomfort and may be indefinite in its localization.

Anorexia—It is almost a constant occurrence.

Nausea and Vomiting—In over half of the cases nausea or vomiting, or both, are present at one time or another.

General Appearance—Usually anxiety is expressed and if the process is extending, a toxic, apathetic appearance is highly suggestive of arising complications.

Distention—Very early this may be absent, but notoriously these patients swallow air and, later, as the toxic process develops peristalsis is affected, causing distention, the result of mechanical and bacterial changes. It is our feeling that this, more than anything else, accounts for the confusing and conflicting findings when palpation is attempted.

Tenderness and Rigidity—Over the involved area tenderness and rigidity can be expected to follow if inflammatory changes are present. The extent should depend upon the acuteness of the process, the involvement of the outer coat of the gallbladder, the presence or absence of protecting organs such as the omentum and the position (superficial to deep) of the gallbladder.

itself Logically, colic without tenderness can be assumed to be free of inflammatory changes Likewise, increasing tenderness and rigidity will follow increasing inflammatory processes As complications develop, exquisite tenderness with definite muscle guarding is present.

A Palpable Mass—This is a most important diagnostic sign. As the inflammation progresses the gallbladder enlarges and localized peritonitis follows, the great omentum may try to protect and localize the process By careful palpation this is revealed as a more or less definite finding The importance which can be attached to this definite or indefinite mass ("inflammatory cake") may depend upon the findings of previous examinations as one watches the course of the disease

Fever and Chills—In the ordinary case of acute cholecystitis there is no chill. The temperature rarely rises above 100° F In the presence of complications, fever and chills usually occur, indicating serious developments such as empyema or gangrene

Leukocytosis—A polymorphonuclear leukocyte increase is almost always present and usually ranges between 15,000 and 25,000

Jaundice—In approximately 20 per cent of cases this is present, but it does not necessarily mean that there is a stone in the common bile duct More often there is not It may result from torsion and bending, inflammatory changes, or a stone in the common bile duct, or possibly a hepatitis

Treatment

All cases should be observed at least once in twenty-four hours until it is certain that the process has subsided If, after forty-eight hours, one is uncertain the patient should be carefully examined every twelve hours All therapy is based upon the principle that elective surgery (or in case of debility, the prevention of surgery) is preferable. Each case, therefore, should be individualized instead of choosing the more risky attitude of immediate surgery in all cases

Bed Rest—This should be complete, except for bathroom privileges in selected cases

Food—A low fat, high carbohydrate, high protein diet should be used In case of nausea and vomiting, complete gastric rest is advisable, substituting for it the intravenous administration

of a 10 per cent solution of glucose in distilled water or normal salt solution (2000 to 3000 cc in twenty-four hours). As soon as it is possible skimmed milk, fruit juices, gelatine preparations, and junket are substituted in small quantities every two hours, making the total daily intake sufficient to cause an excretion of 1000 cc of urine in the twenty-four-hour interval. In this way, dehydration and acidosis will be prevented.

Elimination—Bland enemas are usually the most satisfactory. If gastric tolerance permits, any nonsaline laxative such as the fluid extract of cascara 1 to 2 drams (4 to 8 gm), compound licorice powder 1 to 2 drams (4 to 8 gm) and the like may be used.

Local Applications—Large, thick flaxseed poultices, applied over the entire abdomen, usually give more comfort than any other application. They may be applied for a one-hour period every six to twelve hours, depending upon how much the skin can tolerate.

Medication—For colic give morphine sulfate hypodermically or beneath the tongue in $\frac{1}{4}$ -grain (0.016-gm) doses, as often as needed. For discomfort and less severe pain a capsule containing $\frac{1}{2}$ grain (0.032 gm) of codeine sulfate, $\frac{1}{12}$ grain (0.005 gm) of extract of belladonna and 5 grains (0.325 gm) of acetylsalicylic acid given every three to six hours may be all that is necessary. Sedatives, such as phenobarbital or one of the bromides, may be useful in producing relaxation and in obtaining rest.

Care of Other Organs—In case the prothrombin time is less than 50 per cent, it is important to administer vitamin K in 1 or 2 mg doses by mouth, or into the muscles, or directly into the veins every two hours for two or three times until the test is normal. Occasionally it is necessary to administer whole blood when the damage to the liver cells makes the vitamin K inert.

When the total blood protein is lower than 6 gm per 100 cc one may use human blood plasma, whole blood (or perhaps one of the newer amino-acid preparations which are beginning to offer promise) to improve or correct this state.

In those cases where the urobilinogen content of the urine is present in a dilution greater than 1 to 20, or where there is evident impairment in the ability of liver cells to excrete dye (bromsulf-

alein) or its bile pigment, 10 per cent glucose in normal salt solution or distilled water should be administered intravenously daily in 1000- to 3000-cc amounts. The greater the damage to the liver cells, the more glucose is required. It is important to maintain the blood sugar at a high level in such cases in order that the glucose may be converted into glycogen and stored as a protective agent in the diseased liver cells.

Sulfonamides—At the present time it appears that their use is contraindicated, inasmuch as nausea, vomiting and other toxic effects which may follow their use may be confused with the possibility of an extension of the process, and since from a mechanical standpoint the drugs would fail to reach the involved strangulated part.

Surgical Intervention—Almost always this condition requires surgical methods, unless the risk involved, when one considers the patient as a whole, is greater than the risk of the condition being considered.

Emergency intervention is necessary in those cases in which the sum total of the general appearance of the patient, the temperature, white blood count and the localized findings, especially that of a palpable mass, make one feel that the process is extending and approaching a state where a dangerous complication may occur.

Fortunately, elective surgery can be performed in many cases of cholecystitis, at a time when the acute process has subsided and all abnormal factors have been corrected, insofar as it is possible. This allows the surgeon the freedom to work in a less infected field and to choose those technical procedures which will insure the best possible result.

ACUTE PANCREATITIS

Acute pancreatitis is generally considered an uncommon condition, however, as knowledge of this disease increases we believe that the less severe form is not unusual and is likely to be diagnosed as some more common ailment such as acute cholecystitis. Acute pancreatitis tends to occur in association with chronic disease of the biliary tract (in at least 60 per cent of cases). There may be a history of previous attacks. The symptoms vary in severity somewhat depending upon the type of process in the pancreas. Pathologically the prominent changes

occurring in various cases may be roughly classified as acute edematous, hemorrhagic, necrotic and suppurative

Diagnosis

Pain—The pain of acute pancreatitis frequently follows several hours after a large meal or an alcoholic excess. It is sudden, constant, severe and originates in the epigastrium or upper abdomen and may radiate in any direction, usually it is transmitted straight through to the back. The differential diagnosis is made easier in those few instances with involvement mainly of the tail of the pancreas, where the pain is chiefly in the left side of the epigastrium, with or without radiation laterally. There is a tendency for gradual subsidence of the pain.

Nausea and Vomiting—These are often present and frequently to such an extent that intestinal obstruction may be simulated. Paralytic ileus occurs in the most severe cases.

Swelling, Rigidity and Tenderness—Rigidity and tenderness over the pancreas are likely to be present soon after the onset of pain. They are not as marked as in acute perforation of a peptic ulcer. Swelling of the epigastrium may occur and is likely to be transverse and over the area of the pancreas, tending to follow the rigidity and tenderness.

Prostration and Shock—The degree of prostration may be slight or absent but is usually present to some extent and may vary from actual shock and collapse to death within a period of hours. It had been thought that these patients all suffered from shock but with the increase in frequency of diagnosed pancreatitis it has become evident that this is not true.

Leukocytosis—The white blood cell count averages between 10,000 and 15,000 per cu mm. A count over 20,000 is usually indicative of marked peritoneal involvement or suppuration.

Enzyme Studies—The determination of the blood or urine amylase (diastase) is the most important and reliable laboratory procedure in the diagnosis of acute pancreatitis. The level in the blood is considered elevated when it is well over 200 mg (units). Values over 70 units for urine are significant. The rise of amylase in the first two to twenty-four hours in acute pancreatitis is so constant that its absence makes the diagnosis very unlikely. The level tends to decline after twenty-four to forty-eight hours. Determination of the level of serum lipase is im-

portant but of less value than amylase because a significant elevation may be caused by conditions other than acute pancreatitis.

Peritoneal Fluid—Needle aspiration of peritoneal fluid in search of free blood has been advocated as a procedure for diagnosis of the hemorrhagic type but its value does not merit its use as a routine measure

Treatment

In the severe cases, oral intake is stopped and a suction tube is passed into the stomach. A sedative such as morphine sulfate is likely to be required in large and frequent doses for the relief of pain. Parenteral fluids should be given according to the size of the patient and the amount of vomiting, usually between 2000 and 3000 cc is administered, preferably intravenous normal saline solution containing 5 per cent glucose. About one third of these patients have a disturbance in carbohydrate metabolism and because of this some clinicians feel that the utilization of glucose should be insured by the addition of 15 to 20 units of regular insulin to each liter of glucose solution. In the event of shock, blood transfusions and plasma are indicated. Antispasmodics, such as nitroglycerin grain $\frac{1}{400}$ (0.6 mg), have been suggested for treatment but their value is questionable and they should not be used where shock may occur.

Surgery as an emergency procedure is contraindicated except where there is reason to suspect the presence of another condition amenable to surgery, such as acute perforation of a peptic ulcer or acute appendicitis. Interval operation, after a number of days, may be indicated where there is associated biliary tract disease. At operation biliary obstruction may be relieved by cholecystostomy or the insertion of a T tube in the common bile duct. The formation of an abscess is an indication for surgical drainage.

ACUTE APPENDICITIS

We have tended to expect the manifestations of acute appendicitis to be stereotyped. More consideration should be given to the atypical symptoms and signs, and it is important to remember that this is a disease which affects any age group. Statistics of the misdiagnoses should impress us, inasmuch as a large per-

centage of these fall in the very young and older groups Abdominal pain of any sort should bring to mind the possibility of acute appendicitis

Diagnosis

Pain—This is the first symptom, typically beginning as a colicky, cramplike pain in the epigastric or umbilical regions and shifting to the right lower abdomen where it becomes an aching sensation A characteristic accompaniment of pain at the onset is a sensation of fullness or tension in the rectum or colon, causing a belief that evacuation of the bowel would relieve the pain, hence the frequency of laxative taking We wish to stress that group consisting of approximately 25 per cent of cases in which this sort of pain is not present In the absence of appendiceal distention the early upper abdominal pain is absent The position of the secondary localizing pain is dependent upon the extension of the inflammatory process to the peritoneum covering the appendix and the structures which surround the appendix The pain of pelvic appendicitis may be referred to the midline or to either side of the lower abdomen Frequently the pain from retrocecal appendicitis is localized anywhere from the outer part of the flank, behind the cecum, and at times to the upper right abdominal quadrant The infected appendix which points toward the midline may be associated with pain referred to the left abdomen This is especially true in children

Nausea and Vomiting—It is true that these symptoms usually follow pain, but on rare occasions they may precede the pain and frequently they are absent

Constipation and Diarrhea—For practical purposes these symptoms are unimportant as a rule Too often laxatives may account for the diarrhea In cases of pelvic appendicitis, however, the presence of diarrhea may be of diagnostic help Constipation is no more common than in many other conditions

Tenderness—This should be present in all cases Its extent depends upon the degree to which a patient reacts to pain, the position (superficial or deep) of the appendix and the severity of the process It is a treacherous sign unless we constantly keep in mind the above facts We should like to stress that rectal or pelvic tenderness is important when the position of the appen-

dix is low and deep. A digital examination of the rectum is especially valuable when one is studying a child. Careful and systematic palpation in the flank is necessary if we are to find involvement of the retrocecal appendices. Too often palpation is hurried and incomplete. It should include the entire abdomen, the flanks and a rectal or a vaginal examination.

Muscle Spasticity—This varies from marked to mild increases in muscle tone. It may or may not be present depending to a large extent on the position of the appendix and the degree of its involvement. Its presence or absence should not confuse us if these facts are kept in mind.

Urinary Symptoms—Occasionally the appendix is in contact with the urinary bladder or ureter. This is especially true in children. Frequency of voiding and dysuria may occur in those instances in which the process extends by contact to the bladder. If the appendix reaches the ureter, red blood cells may be found in the microscopic examination of the urine.

Fever—Very early in its course, the temperature varies from normal to 1° to 2° F above normal. After the formation of pus, gangrene, perforation, or abscess, the temperature reaches various heights, depending upon the inherent resisting powers of the patient and the complication which follows.

Leukocytosis—Usually there is an increase in the polymorphonuclear cells, the total white count averaging from 12,000 to 18,000. On the other hand, there may be no increase, a relative increase in the polymorphonuclear cells, or the white blood count may be more than 20,000.

Management

We would like to stress that a patient having abdominal pain should be seen at once and the typical and atypical features complained of or discovered should be carefully considered. In so doing most cases can be immediately diagnosed and treatment instituted. When there is a reasonable doubt about the diagnosis, the patient should be placed in bed, given an ice bag or hot water bottle to apply to the abdomen, sips of fluids, and if necessary to appease the family some drug such as 5 grains (0.325 gm) of sodium citrate every two hours. A review of the diagnostic problems should be made every few hours. Until a diagnosis is made, pain-relieving drugs should be avoided. After-

wards, in case the patient has agreed to surgical intervention, opiates may be administered

The proper treatment is early hospitalization and surgical intervention with or without the use of sulfonamides depending upon whether a complication has arisen prior to the proper treatment. At the present time there is no reason to believe that this newer drug therapy will supplant early operative intervention.

ACUTE INTESTINAL OBSTRUCTION

Acute obstruction may occur in any part of the gastro-intestinal tract, but most frequently occurs in the terminal ileum. Its causes are many and include those conditions which cause obstruction in the lumen by involvement from without, such as hernia, intussusception, volvulus, adhesions and the like, conditions involving the coats of the intestines and producing obstruction such as strictures, tumors and the like, and those rarer mechanical disturbances which obstruct the lumen itself such as foreign bodies, fecal impactions and gallstones. Variations in the character of the symptoms depend upon the site of the obstruction and its cause.

Diagnosis

Pain—The pain is usually sudden in onset, at first colicky in character and later becomes continuous and is severe. The point of maximum severity is over the point of obstruction, but when an acute process is superimposed upon a chronic one, the pains are often epigastric, perumbilical, or across the lower abdomen—depending upon the site of obstruction.

Vomiting—Reflex emptying of the stomach tends to follow soon after the onset of pain. Gradually vomiting becomes obstructive in type with explosive, forceful emissions of mucoid, biliary green or finally fecal material (frequently after twelve to twenty-four hours) especially where the site of obstruction is below the midileum.

Constipation—In cases of low obstruction this may be complete, higher ones may be associated with the passage of material left below the site of obstruction. In cases of intussusception, the passage of blood has great diagnostic value.

Shock—A toxic protein substance is liberated from the distended injured loop of the bowel in instances where the blood

supply is interfered with. This is probably responsible for the rapid progression to shock and death in certain cases. The patient appears anxious, the skin may be clammy, the tongue dry, the pulse increases, and the blood pressure falls.

Abdominal Signs—In cases of high obstruction there is usually slight upper abdominal distention. When the terminal ileum is involved the distention is apt to be more central and at times the "step-ladder-like" appearance may be seen. When the colon is involved, distention is likely to be more general and at times the colon may be seen to be distended, giving the appearance of an inverted U.

By palpation one may be able to feel a herniated pouch or a distinct mass. Early, the tenderness is found over the site of the obstruction and later it is apt to become general.

In the uncomplicated cases of acute obstruction, peristaltic sounds are absent, but when obstruction is superimposed upon a chronic process, hyperactive and high-pitched tinkling sounds are heard until complete paralysis occurs.

Blood Findings—A leukocytosis occurs and may reach very high levels (70,000 to 80,000). The blood nitrogen increases rapidly in high obstruction and is usually normal or minimal in low obstruction. The vomiting and outpouring of fluids into the bowel is accompanied by a loss of circulating blood electrolytes, especially the chlorides, causing an alkalosis.

Roentgenogram—In films of the abdomen may be seen distended loops of bowel with the characteristic "feathered" or ribbed appearance of the Kerkring folds in the small intestine. Dilation over a large length of intestine may give the form of a "spiral spring." A study of films taken with the patient in the upright position may show fluid level lines surmounted by dome-shaped gas bubbles. The distended large bowel is usually peripherally placed and shows haustral markings, however, a barium enema is often necessary for differentiation.

Treatment

Diagnostic procedures should be carried out promptly in all cases of suspected intestinal obstruction. Normal saline solution (with 2.5 to 10 per cent glucose) intravenously and transfusions of blood or plasma are necessary especially in cases of "high" intestinal and strangulation obstructions for replacement of

chlorides, to combat alkalosis and dehydration, to aid kidney function and to restore blood volume

Surgical Intervention—Immediate operation is indicated in all cases of obstruction by strangulation and in massive distention of the colon. In other cases decompression with the Miller-Abbott tube should be started. Wangenstein states that all cases, except those with strangulation and massive distention of the colon, should have twenty-four to thirty-six hours of decompression and then surgical intervention if the measure is unsuccessful. The danger that intestinal intubation with suction-siphonage may obscure obstruction with interference of the blood supply must be kept in mind, and cases showing a continued toxic reaction with prostration, fever, leukocytosis, and continued pain should be submitted to operation just as soon as the fluid and electrolyte balances are established.

OBSTETRICAL EMERGENCIES FROM THE STANDPOINT OF THE GENERAL PRACTITIONER*

EDWARD A. SCHUMANN, M.D., F.A.C.S†

THIS clinic is to deal with the major problems of obstetrics as they confront the general practitioner of medicine who finds his obstetrical commitments greatly augmented by reason of the war on account both of the shortage of physicians and the sharp increase in the national birth rate

The major anxiety which arises in the conduct of a maternity is the maintenance of the health of the mother and the avoidance of maternal mortality. Most causes of maternal death fall under the three main categories—toxemia, hemorrhage and sepsis—which will account for the great majorities of fatalities, all other causes combined constituting but a comparatively negligible proportion.

Happily, at least two of these disease entities have been robbed of much of their terror by modern obstetric methods, although hemorrhage still remains a serious factor.

TOXEMIA

The mortality of eclampsia has been markedly reduced but this condition still carries with it a very definite danger to life. The greatest improvement has taken place in the lessening of the number of toxic patients as a whole and in the still greater reduction in the proportion of toxic women who go on to eclampsia. It is a most significant fact that, whereas thirty years ago eclampsia was almost always present in the maternity hospitals of Philadelphia, it is now so uncommon that many interns and residents pass their entire term of service without seeing a single case or at worst a very, very few.

* From the Kensington Hospital for Women and the Protestant Episcopal Hospital, Philadelphia.

† Surgeon-in-Chief, Kensington Hospital for Women, Chief of service in Gynecology and Obstetrics, Protestant Episcopal Hospital.

Prevention of Pre-eclamptic Toxemia

This improvement in outlook may be summed up in the two words, *prenatal care*. If we except the cases of toxemia resulting from a pre-existing nephritis or hypertensive vascular disease (in which the only really successful treatment lies in the prevention of conception or the early termination of pregnancy), pre-eclamptic toxemia may be prevented in all but a very small percentage of patients.

The theories as to the etiology of this toxemia are legion but only one of them seems to fit all the facts. It is my very deep conviction that pre-eclamptic toxemia is a nutritional disease per se and that it rarely develops when pregnant women are properly fed from the early weeks of gestation. It is true that many lesions may be found in these women *after* the toxemia has begun to disclose itself. Thyroid deficiency, pituitary imbalance, placental infarcts—all of these are present singly or in combination, but they are all probably secondary to disordered nutrition.

Diet—Too little attention has been paid to the work of Winslow Tompkins of Philadelphia whose careful studies of many clinic patients and painstaking appraisal of the results obtained seems to fairly definitely point to the conclusion that by proper diet plus intake of certain vitamins, the occurrence of toxemia may be cut to a minimum. This diet is as follows:

Morning Meal or Breakfast

Grapefruit or an orange

One slice of bacon

One slice of whole wheat bread or toasted bread with a small amount of butter

One cup of coffee or kaffee hag

Noon Meal or Luncheon

Cold sliced ham or chicken (small portions)

One green vegetable, or instead, lettuce salad with a small amount of cheese

One slice of whole wheat bread or stale bread with a small amount of butter

One-half glass of water

Evening Meal or Dinner

Strained soup if desired

Fish, fowl, game or lamb

Two of the following vegetables: asparagus, broccoli, brussels sprouts, celery, green peas, kale, lettuce, spinach, squash, string beans, sorrel, Swiss chard, or water-cress

Bread (a small portion)

For *dessert* may take fruit, either raw or stewed (except strawberries and bananas), jello, junket, or cup custard (not sweet)

Of *fluids*, may take a half-glass of water

1 No liquid at mealtimes except as indicated above

2 A glass of pure water on rising and three hours after each meal

3 A hot bath every second night on retiring, followed by active hand rubbing

4 A walk in the open air twice daily

The Management of Pre-eclamptic Toxemia

Pre-eclamptic toxemia is manifested by a persistent rise in blood pressure, though this may be of slight degree. A continuing elevation of 15 to 20 points systolic above the norm for the woman, together with the appearance of pretibial and facial edema, an increase of weight exceeding 1 pound per week in the latter months of pregnancy and the onset of albuminuria constitute the primary signs. A sense of malaise may be present. Such signs indicate the necessity for prompt treatment. Due attention to diet, with a reduction in total food taken, the almost complete elimination of carbohydrates and sugars, but an abundance of proteins is the first step. The limitation of liquid intake to 40 ounces per twenty-four hours, and free purgation with magnesium sulfate are of great value. Bed rest, preferably hospitalization for a few days, is indicated. During this time the kidney function should be studied in detail, urea clearance tests being of great importance.

Under this plan the incipient toxemia often subsides and the evidences of its presence have disappeared after six to ten days. The patient then is permitted to resume her usual activities, reporting once weekly to her physician and maintaining a strict dietary regimen. Should the toxemia recur, the same procedures are to be repeated. Occasionally several such episodes may develop during the last four months of pregnancy and yet result in a normal accouchement at term.

Sometimes, however, the toxic signs persist and although the progress of the disease seems to be arrested, there is little or no improvement. In such instances the welfare of the infant becomes a paramount interest and it is well to induce labor as soon as may be after the period of viability of the child has been reached. Clifford and others have shown conclusively that the probability of securing a healthy baby from a toxic mother decreases almost in direct ratio to the duration of the toxemia as well as

its severity "Better a healthy premature baby than a toxic one at term"

If in spite of treatment the toxemia grows worse, and increasing edema, diminution of urine output, increase in albuminuria and in blood urea nitrogen, headache, epigastric pain and possibly albuminuric retention herald the approach of eclampsia itself, more vigorous treatment should be instituted at once. The diet is sharply reduced and consists of skim milk with an occasional bowl of purée of some green vegetable as spinach or asparagus. Purgatives with saline should be provided daily. The intravenous injection of 1000 cc. of 5 per cent glucose solution daily is of value. Should the patient evince a beginning restlessness, eclampsia is imminent and vigorous sedation is advised.

The Treatment of Eclampsia

The treatment of eclampsia itself is based upon the following essentials

- 1 The elimination of toxins.
- 2 The control of convulsions
- 3 The maintenance of the circulation
- 4 The prevention of injury to the patient during periods of unconsciousness
- 5 The preservation of the life of the child if possible
- 6 The prevention of permanent damage to the kidneys

Happily, most patients in eclampsia go into labor spontaneously, this being Nature's method of eliminating the source of the toxemia. In those who do not develop uterine contraction, induction of labor by rupture of the membranes or the insertion of bougies is feasible, but not in the case of primigravida with long canalized cervixes and no effacement. Surgical methods of procuring delivery, as accouchement forcé, are inadvisable because the eclamptic woman withstands trauma badly.

The elimination of toxins is aided by free purgation by copious colonic lavage using large quantities of water and sometimes by sweating by means of the hot dry pack followed by careful toweling to dryness and a complete change of bed clothing.

For sedation a modification of Stroganoff's technic is employed in these clinics. Magnesium sulfate, 20 cc. of a 10 per cent solution, is administered intravenously at four-hour inter-

vals, not more than 10 cc of the salt being given in twenty-four hours

Morphine sulfate, grain $\frac{1}{4}$ hypodermically, is exhibited at intervals of from one to four hours, depending upon the reaction of the patient. A respiratory rate of 12 per minute and/or a pulse rate of 60 or below reveals that the therapeutic limit of morphine has been reached and the drug must be discontinued until elimination takes place. Phenobarbital in doses of from 6 to 10 grains is a useful adjunct to the morphine.

Every care must be taken that the patient in convulsions may suffer no injury. A padded spoon handle or tongue depressor kept between the teeth will prevent tongue or cheek biting. Restraint by sheets may save an injury from a fall from the bed and whenever possible the crib type bed should be used.

As soon as she can swallow, the patient is given water freely and the parenteral use of fluids is advised. Failing circulation is supported by digitalis which also acts as a diuretic. In a florid woman with great general congestion and a laboring right heart, venesection with the withdrawal of 1000 cc of blood often is of great benefit.

During the entire course of the eclamptic attack, the patient should be kept in a quiet, semidarkened room and carefully protected from chilling.

Ordinarily, such a course of treatment will be followed by a gradual cessation of convulsions, return to consciousness, and an increased urine output. Somewhere during the attack labor and delivery have usually taken place and improvement thereafter is rapid.

The Place of Cesarean Section in Eclampsia—Speaking generally, cesarean section, or indeed, any major operative procedure has no place in the management of eclampsia. However, there are some women who do not improve at all under the conservative treatment as outlined above, and in whom vaginal delivery is impracticable by reason of the undilated and un-effaced cervix, cephalopelvic disproportion, or other causes. Here I feel that cesarean section has a distinct place and the operation when performed under local anesthesia sometimes is responsible for the recovery of a woman in whom all other phases of treatment have failed. Such cases are few and the writer insists that he does not advocate abdominal hysterotomy as a treatment.

for eclampsia per se, but only employs it when all other measures have failed

The Subsequent Management of Eclamptic Women—Close and persistent follow-up observation is necessary in all cases. Many patients recover completely, blood pressure, weight, urine all becoming normal within a few weeks. These women may be dismissed with the advice that they avoid pregnancy for at least one year, and should conception occur they should at once place themselves under the care of a competent physician, informing him of their previous toxemic episode.

Those patients who do not recover and in whom there are evidences of permanent kidney damage or vascular disease in general, should be advised to consult an internist at once and be guided by his advice as to their future.

THE HEMORRHAGE OF PREGNANCY

The etiology of bleeding during pregnancy varies with the period of gestation and, for the purpose of diagnosis, it is well to consider pregnancy in its three trimesters and to classify the causes of hemorrhage in each according to their relative frequency.

In the first three months, by far the most common cause of uterine bleeding is threatened or inevitable abortion, the second is ectopic pregnancy. These two account for more than four fifths of all hemorrhages. Next in point of frequency are hydatidiform mole, persistence of menstruation, menstruation from one horn of a double uterus, uterine polyps and cervical erosion or carcinoma, all of which are uncommon.

Differential Diagnosis of Threatened Abortion and Ectopic Pregnancy

Although the classical picture of abortion shows pain, hemorrhage and dilatation of the os, it is noteworthy that in many instances painless bleeding may persist for several weeks, before complete separation of the ovum, or its death inaugurates uterine contraction with the development of the other two elements of the syndrome.

Hemorrhage in abortion may be furious, with rapid exsanguination of the patient, but I have never yet seen a fatality from this accident which could be ascribed to hemorrhage alone. When infection occurs, the prognosis among women with severe

anemia becomes very grave, but bleeding without infection is rarely a cause of death

The diagnosis of abortion with hemorrhage may be made by the elicitation of the signs and symptoms of pregnancy in the first trimester plus the findings of some degree of dilatation of the cervix on bimanual examination and the history of pain and bleeding. If fragments of decidua or placenta are found, the evidence is conclusive. The most important condition with which uterine abortion may be confused is ectopic pregnancy and the differentiation of these conditions is often difficult.

The classical picture of ruptured ectopic pregnancy—sudden, catastrophic pain, with fainting and collapse—is seen in slightly less than half of all cases, the more common symptoms being a dull but increasing abdominal pain, rigidity of the recti muscles, slight elevation of temperature and a moderate or high leukocytosis. Associated with these symptoms is vaginal hemorrhage, which although it may at times be fairly profuse, is never violent. Indeed, one of the valuable signs for differentiation is the fact that the woman suffering from ectopic pregnancy may, and frequently does, show the effect of severe blood loss, although the visible hemorrhage is negligible, whereas in intra-uterine abortion, the evidence of anemia is in direct ratio to the visible amount of blood.

The history in these cases is also most important from a diagnostic standpoint. In abortion, there is complete amenorrhea, with the associated subjective signs of pregnancy—nausea and vomiting, polyuria, pain and tingling in the breasts and increased vaginal secretion. In ectopic pregnancy the signs of pregnancy are vague, usually—at least not so pronounced as in uterine gestation. The amenorrhea is generally not complete. The patient will state that she has missed a period, but noted some slight spotting a week or two later, which has been repeated in greater amount before the onset of pain.

On bimanual examination, the uterus in abortion is definitely increased in size, is soft and globular in outline. The cervix is velvety and dilated to a varying extent. There may be some cyanosis of the cervical and vaginal mucosa, and Hegar's sign—obliteration of the lower uterine segment—may be present. Ladin's sign, a small area of marked softening in the anterior wall of the cervix and lower uterine segment, is a common find-

ing In ectopic pregnancy, the uterus is generally only slightly enlarged and the characteristic boggy density is not noted. Movement of the cervix is often quite painful, and palpation of the adnexa may or may not reveal the presence of a tender, soft, spindle-shaped mass. If there has been a considerable accumulation of blood in the pelvic cavity, the cul-de-sac may bulge, with a doughy sensation being imparted to the examining finger.

The nature of the pain in the two conditions is often very valuable in diagnosis. In abortion the pain is intermittent, cramp-like, and the patient likens it either to menstrual cramps or labor pains. In ectopic pregnancy the pain is at first to one side or the other of the midline and then becomes a generalized abdominal ache, as free blood in the peritoneal cavity causes irritation and mechanical peritonitis.

Management of Abortion with Hemorrhage

The management of abortion with severe hemorrhage is usually restricted to packing the vagina firmly with gauze or cotton, under aseptic precautions, the packing to remain in place for twenty-four hours, after which the products of conception will often be found lying free in the vagina, upon the removal of the gauze. When the abortion occurs at the end of the third month, or early in the fourth, the placenta may often be found lying in the cervical canal and presenting as a tightly rolled cylinder, simple extraction with the fingers or a ring forceps, in this circumstance, often stops the bleeding. The administration of ergot, especially the newer ergonovine preparations, will do much to contract the uterus and aid the extrusion of the ovum. If fever is present, the sulfa drugs should be administered.

Curettage is not often necessary, although it may be required in the presence of persistent bleeding. Although this is a minor operation it requires considerable skill and care, for perforation of the pregnant or puerperal uterus is by no means an uncommon accident.

Management of Ectopic Pregnancy

The management of ectopic pregnancy requires little comment. Prompt laparotomy upon the establishment of the diagnosis is the rule. One point of importance is that, in the interval between the occurrence of the hemorrhage and operation, there

should be no stimulation or intravenous therapy practiced Morphine to secure rest, elevation of the foot of the bed, and external heat are valuable measures, but stimulation should be reserved until the patient is prepared for section, when blood transfusion, 10 per cent glucose intravenously and cardiac stimulants may be used freely.

Hydatidiform Mole

Hydatidiform mole is a somewhat uncommon, but very definite, source of uterine hemorrhage. The *diagnosis* may be confirmed by the fact that the uterus is considerably larger than normal for the duration of the pregnancy, that the patient has experienced more than the ordinary degree of nausea and vomiting, that the Aschheim-Zondek or Friedman test is positive with greatly diluted urine (one tenth the usual amount) and that, if the pregnancy be of more than sixteen weeks' duration, roentgenologic examination will fail to show centers of fetal ossification. The passage of the little cysts which constitute hydatidiform mole is conclusive evidence.

The *treatment* of mole is immediate removal of the growth, per vaginam possibly, but better by abdominal hysterotomy under local anesthesia, the mole being removed under vision. It is almost needless to say that all such cases should be closely watched, with periodic Friedman tests, to determine the possible signal of chorionepithelioma.

The other causes of bleeding during the first three months which I have mentioned are uncommon and may usually be recognized with ease by a speculum examination.

In the second trimester, abortions still take the lead as a cause of hemorrhage, closely followed, as this period draws to a close, by the bleeding from placenta praevia. Ectopic pregnancy, polyps and so forth may be responsible, but not commonly so, since their presence has been usually disclosed earlier.

Placenta Praevia

Diagnosis—After the fifth month, placenta praevia must always be uppermost in the mind of the obstetrician when uterine bleeding is present. Here the classic symptom is painless bleeding, often slight in amount at the first attack, with irregularly recurring hemorrhages of increasing severity. The diag-

nosis of placenta praevia so early in pregnancy offers great difficulty. Since endometritis is an etiologic factor, a history of preceding abortions or uterine disease is of some value. The condition occurs far more commonly in multiparas than in primiparas, and the bleeding is always painless, and seemingly without cause, although coitus or excessive muscular exercise may precipitate a hemorrhage.

When there is grave doubt, the *roentgenologic method* of diagnosis as described by Ude and Urner is of great value. Their technic is to instill into the empty bladder about 40 cc. of a solution of sodium iodide (12.5 per cent) or other contrast material. An anteroposterior film of the pelvis is now made, the catheter having been first withdrawn. In normal pregnancy, the presenting head lies almost in contact with the bladder, the intervening space occupied by the lower uterine segment, the space between bladder margin and fetal head appearing to be about 6 to 8 mm. in length. In placenta praevia, the mass of the placenta, its concave border upward, lies between the fetal head and the bladder, separating the two by a space of varying width, depending upon the thickness and location of the placenta, and clearly visible on the x-ray film. This method constitutes a distinct advance in the diagnosis of placenta praevia, especially because it involves no vaginal manipulation, which might favor separation or lead to infection. The soft tissue x-ray which discloses the location of the placenta, especially upon the lateral view, is of great value in diagnosis.

Lacking roentgenologic facilities, the diagnosis must depend upon the history, the nature of the bleeding, and auscultation with possible demonstration of a placental bruit low over the symphysis. The discovery, upon vaginal examination, of a soft doughy mass lying between the head and the cervix will confirm the diagnosis, but this is a dangerous maneuver and should not be undertaken unless the accoucheur is prepared to deal at once with dangerous hemorrhage.

Treatment—The treatment of placenta praevia constitutes one of the major problems of obstetrics and the management of this lesion before the complete viability of the child is a very perplexing one. It has been well said that there is no expectant treatment of placenta praevia, and one or two bitter experiences with attempts to temporize in such situations have amply con-

vinced me of the correctness of this axiom. What is to be done with the young woman, a primipara, let us say, who is in the seventh month of her pregnancy, ardently desires a child, and develops the characteristic signs of placenta praevia? It is true that in many instances a tranquil life, avoidance of coitus, vigorous exercise and the use of cathartics will allow pregnancy to continue to term or nearly so, without serious hemorrhage. It is also true that such patients may suffer a tremendous blood loss, of dangerous or even fatal volume, at any moment, bleeding sometimes occurring during sleep. Nor is there any procedure available by which such accident may be forecast.

It follows then that pregnancy should be terminated as soon as the diagnosis is made, either by abdominal hysterotomy, or by induction of labor, depending upon the degree to which the placental mass covers the cervical canal. On the other hand, the desire to conserve the life of the infant, religious objections, and the fact that pregnancy may continue without disturbance render such radical treatment quite distasteful, so that I have come to the conclusion that the best plan available is to explain the situation to both parents in great detail, and to require that the final decision come from them. For the protection of the physician against future criticism, should disaster follow conservative management, it is well to have the prospective mother and father state their wish in writing.

When the first hemorrhage occurs after the child is viable, a different problem arises. Undoubtedly, the best prognosis to mother and infant is offered by cesarean section, preferably of the classical type, performed under local anesthesia by one fully trained in major obstetric surgery and in a qualified hospital. This applies to all cases, except those occurring in multiparas with partial placenta praevia, where there is an available area of the cervical canal occupied by the membranes alone, thus permitting the induction of labor by simple rupture of the membranes or by the insertion of a dilating bag. As my own experience grows, I find myself rarely regretting the decision to deliver by section, while sometimes wishing this method had been chosen rather than the finally selected vaginal route.

In those emergency cases wherein the obstetrician is faced with the problem of serious hemorrhage with beginning labor, in a locality where prompt and efficient section is not available, the matter is serious indeed. Here there are several procedures

available, none of them quite satisfactory but necessary as emergency measures. They are as follows: simple rupture of the membranes with the use of small doses of pituitrin, subcutaneously or by the nasal route, Braxton-Hicks version, the use of the metreurynter or dilating bag, and as a last resort, vaginal packing together with the use of a tight abdominal binder.

Simple rupture of the membranes, the Rotunda method, sometimes permits the descent of the head to act as a tampon and, when combined with pituitrin to maintain uterine contraction, is of much value.

The Braxton-Hicks version—turning the child and drawing down a leg until the buttocks make pressure upon the placenta—works well for the mother but is extremely hazardous for the child, and is not available unless there be sufficient cervical dilatation to permit the entrance of two fingers into the uterine cavity. It should be remembered that extraction of the infant after this type of version is dangerous and that delivery should be left to the forces of nature insofar as possible.

The use of the dilating bag was strongly advised by the late Dr. Cragin, who achieved great success with this treatment. The folded and lubricated bag should be passed alongside of the placenta if this be possible, or should be plunged through the mass of that organ if the praevia is central. The violent hemorrhage excited by perforation of the placenta is dealt with by rapidly filling the bag to capacity with an antiseptic solution and attaching a weight to the tube to insure strong pressure against the placenta from above.

Vaginal packing is a last resort, as has been said. If hospital facilities are not available, if the cervix is elongated and undilated and the hemorrhage furious, it is proper to pack the vagina fully and firmly, using due precautions as to asepsis, and then to apply a very tight abdominal binder. This plan may serve to compress the placental site between the packing below and the uterus which has been forced down from above, and is a device which, while not generally advised, may be life-saving if no better plan of treatment offers.

Abruptio Placentae

In the last trimester, placenta praevia and abruptio placentae are the chief causes of uterine bleeding. Abruptio placentae, which is a premature separation of the normally implanted

placenta, is a somewhat uncommon accident which may rarely arise as a result of trauma, more frequently is said to be due to some form of toxemia, but often occurs without demonstrable evidences of such toxemia or even of degenerative changes in the placenta itself.

This accident, the concealed hemorrhage of the older writers, usually occurs during the last month of pregnancy, sometimes earlier. It is characterized by hemorrhage, not necessarily great in visible amount, but always associated with pain, more or less severe in type.

The separation usually takes place suddenly, the woman experiencing a sharp, lower abdominal pain, which steadily increases. The uterus becomes hard, often described as ligneous, and is tender to palpation, the fundus becoming flatter and broader. Fetal movements and heart sounds disappear and a trickle of blood escapes between the membranes and the uterine wall and appears at the vulva.

If the separation is extensive, the evidences of internal hemorrhage develop rapidly, the air hunger, leaking skin, pallor and falling blood pressure attesting to the profound anemia. As the separation becomes more nearly complete, the presence of blood in the uterus may force a large vaginal bleeding with many clots. *Abruptio placentae* is a matter of grave moment, both maternal and fetal mortality being exceedingly high.

The only available *treatment* is immediate delivery, per vaginam, if happily the cervix is sufficiently dilated to permit of forceps extraction, or abdominal hysterotomy. In the latter case, the uterus is often so infiltrated with blood that hysterectomy becomes necessary.

COMPLICATIONS OF THE THIRD STAGE OF LABOR

Retained Placenta

If the placenta has not been expelled thirty minutes after the birth of the child it is said to be retained. The first step in securing delivery of such placenta is the Credé maneuver. This consists of grasping the fundus uteri through the abdominal wall with both hands and making rhythmical, gentle but firm pressure, in an attempt to reduce the volume of the uterus and so compel it as to dislodge the placenta and force it through the cervix.

The pressure should never be rough and should never be continued more than ten minutes, five is better. In the intervals between pressure, the fundus may be gently massaged with a circular motion in order to stimulate the muscle fibers to contract.

Credé expulsion failing, the next step is manual extraction of the placenta. For this purpose the patient, usually still somewhat under the influence of a sedative (nitrous oxide anesthesia is occasionally necessary), is replaced in stirrups, rescrubbed and redraped. The operator is also scrubbed.

INVASION OF THE UTERUS AFTER DELIVERY IS MORE DANGEROUS THAN BEFORE, SINCE THE ENTIRE INTERNAL CAVITY HAS BEEN CONVERTED INTO ONE GREAT SUPERFICIAL WOUND.

With meticulous asepsis the hand is introduced into the vagina. The cervix may be contracted and the detached placenta simply incarcerated within the uterus. In such cases, the cervix may be gently dilated with the fingers and the placenta withdrawn, continued pressure being made on the fundus by an assistant. (This accident is very rare in our experience.)

Generally the cervix easily admits the fingers which then feel the margin of the placenta, and being inserted beneath it, gently, with a sort of wiggling motion, peel the placenta from the uterine wall. Sometimes only a portion of the organ is adherent, sometimes the entire area. The placental site is palpated for remaining fragments which are pinched off with the finger or removed with placental forceps if this be required. Often there is free bleeding after an adherent placenta has been delivered, and packing should be used without hesitation. Four grams of sulfathiazole introduced into the uterus with the packing tends to inhibit the development of sepsis.

Placenta Accreta—Rarely there is such intimate connection between placenta and uterine wall that no line of cleavage can be palpated and the organ will not peel off the uterus. When this is discovered all attempts at manual removal must cease at once, and the uterus packed with gauze after the instillation of sulfathiazole, the cord ligated close to the vulva and cut. The subsequent treatment may be hysterotomy or expectancy, this to be determined later. All patients with retained placenta should be specially observed for twelve hours after delivery, as late hemorrhage is not infrequent.

Postpartum Hemorrhage

There are two common varieties of postpartum hemorrhage. One consists of massive bleeding immediately after the third stage of labor, which is very alarming but not too dangerous because immediate active treatment is always instituted. The other is a mild bleeding which is not alarming but which does not quite cease. Some hours pass, nurses and physicians go off duty and the newcomers are not aware of the amount of blood loss which the patient has suffered. Suddenly there is collapse and death from hemorrhage, although at no time has there been any severe bleeding.

To prevent this accident it is a rule of the service that in cases of postpartum hemorrhage the physician who conducted the delivery is solely responsible for the patient until the bleeding has definitely ceased.

Treatment of Postpartum Hemorrhage—Haste, packing and transfusion are the essentials of treatment. The moment the obstetrician feels that undue bleeding is occurring he should begin treatment as follows:

One ampule of ergonovine or another of the newer ergot alkaloids is injected intravenously.

The fundus uteri is firmly grasped through the abdominal wall, one hand behind the fundus and one in front. The uterus is then strongly compressed and at the same time pulled upward and forward. After five minutes the bleeding may have greatly lessened and the pressure may be relaxed, the uterus being continually palpated to discover relaxation.

If bleeding persists, the patient is placed in stirrups, scrubbed and draped and the prepared operator examines the cervix, single speculum and ring forceps being used to grasp the lips of the organ. Should the bleeding arise from a laceration of the cervix, this is repaired with interrupted catgut sutures.

If the cervix is not the source of the hemorrhage the uterus must be firmly packed with gauze packing $2\frac{1}{2}$ inches wide and using four thicknesses of gauze. The packing is best introduced with the fingers, care being taken to pay out the gauze over a forceps held by an assistant so that it is not contaminated by rubbing against the labia.

The uterus is packed until the thrust of the fingers is clearly felt by an assistant with hand palpating the fundus through the

abdominal wall and until no more packing can be introduced. If the fingers do not suffice, a packing forceps may be used but in this event great care must be exercised lest the forceps perforate the soft uterus.

Should the bleeding persist and soak through the packing, the latter should be withdrawn, clots wiped out of the uterine cavity and the packing replaced even more firmly than before (under aseptic precautions, of course). Sulfathiazole, 4 gm., may be introduced with the packing. While this is proceeding, preparations for blood transfusion or plasma injection are going forward so that the transfusion may be started even while the uterus is being packed or as soon thereafter as may be. Glucose in saline may be used if blood is not immediately available. Heart stimulation, lowering of the head of the bed, application of external heat and other supportive treatments are carried out.

Ergonovine is exhibited hypodermically every four hours for two or three doses. If all goes well the packing may be removed in twenty-four hours.

If, in spite of these measures, bleeding continues and the patient's condition becomes desperate, hysterectomy may be imperative.

GENERAL MEASURES

General measures have not been mentioned previously in the management of the hemorrhages of pregnancy and labor because these measures are used in the same manner in all cases of excessive bleeding.

Modern obstetrics demands that in every case of uterine bleeding blood transfusion must be immediately available. The securing of blood donors, then proper matching and typing, should run parallel to the first evidence of abnormal bleeding. Blood should be used freely and abundantly and plasma must also always be on hand.

The parenteral installation of supportive fluids such as 5 per cent glucose in saline is a most important adjuvant in the treatment.

PUERPERAL SEPSIS

This dreaded complication of labor has happily lost much of its terror since the sulfa group of drugs has come into common use, but even with this great advance, sepsis still remains one of the great causes of maternal death.

The prophylaxis against sepsis—the meticulous care in preparing the patient for delivery, the reduction of vaginal examinations to an absolute minimum and their conduct under the most scrupulous aseptic technic, the avoidance of contamination during delivery, especially if this be operative in nature, the aseptic technic of the puerperium—all of these are so well known to the profession that further discussion is unnecessary here. Suffice it to say that once the significant chill and febrile temperature have appeared, in spite of all precautions the most unremitting care in both diagnosis and treatment is required if the patient's life is to be saved.

Prompt diagnosis is a *sine qua non*. Pyelitis must be eliminated by frequent examination of catheterized specimens of urine, the upper respiratory tract must be studied to discover a possible lesion and extraneous inflammatory foci such as appendicitis and cholecystitis must be ruled out as must be the exanthemas.

When the diagnosis becomes apparent the treatment may be epitomized as follows (in hospital practice the patient has been isolated upon the first appearance of pyrexia)

- 1 Repeated blood transfusions consisting of 200 cc of citrated blood daily or 300 cc every other day, or plasma in similar amounts. Should there be a reaction of any degree after blood transfusion the Rh factor in the blood must be investigated.
- 2 Sufathiazole or sulfadiazine 4 to 8 gm in twenty-four hours by mouth, guarded by daily estimation of the drug blood level.
- 3 Maintenance of fluid balance by intravenous injections of 5 per cent glucose in normal saline, at least 1000 cc in twenty-four hours.
- 4 Relief of pain and securing of rest by use of barbiturates, or by morphine if necessary.
- 5 Bowels moved by enemas.
- 6 Light diet.
- 7 Postural change, external heat and similar measures to promote bodily comfort.
- 8 Repeated blood cultures to determine course of the disease.
- 9 Regular pelvic examination to discover localized collections of pus, which when found should be drained promptly.

Extensive operative procedures such as hysterectomy and ligation of the veins of the broad ligament are not advised

It is essential that a septic patient be kept at rest until the temperature has been normal for at least three days, the leukocyte count again reaches the norm, and the sedimentation rate has lost its sharp curve. Failure to observe this rule too frequently results in disaster from pulmonary or cerebral embolism.

Many more complications of maternal care confront the practitioner, which may not be considered here for lack of space. Dystocia in its varied forms, rupture of the uterus, inertia uteri and severe lacerations are constant attendants upon an obstetric practice, but all can be successfully managed by careful study of the condition and its prompt treatment. Care in observation and a thoughtful weighing of symptoms and signs are the keynote of success.

ACUTE ENDOCRINE DISTURBANCES

CHARLES WILLIAM DUNN, M.D., F.A.C.P.*

ACUTE or emergency phases are seldom seen in many endocrine disturbances, but there are a limited number, such as Simmonds' and Addison's diseases and parathyroid tetany, in which the clinical picture is frequently associated with acute or emergency states requiring prompt and active therapeutic intervention in order to prevent a fatal outcome. Indeed, there are those who hold that in spite of therapy every case of Simmonds' disease has a fatal prognosis.

The fact that the more common endocrine disorders seldom present acute phases does not relieve us from appreciating the possibility of an emergency or acute state arising during the course of a presumably chronic endocrine state. It is therefore required that the internist, the neurologist and even the surgeon as well as the endocrinologist be mindful of the fact that occasionally a patient with a chronic form of endocrine disease can develop an acute clinical state which can mimic a classical syndrome for which they would ordinarily advise emergency operative therapy. Acute endocrine disturbances are consequently important from both a diagnostic and a therapeutic viewpoint.

There is another aspect of acute endocrine disturbances which has received all too little attention, namely, the exaggerated physiological and/or toxic effects which can occur following the administration of many therapeutic agents of the endocrine group. The possibility of the production of these effects is becoming all the more evident as the utilization of endocrine preparations becomes more general. In fact, the introduction of synthetic chemical products possessing definable hormonal action, in spite of the fact they are not known body

* Associate in Medicine, Graduate School of Medicine, University of Pennsylvania, Endocrinologist, Graduate Hospital of the University of Pennsylvania and Abington Memorial Hospital

constituents or its products, intensifies the need for recognizing this danger in endocrine therapy

THE HORMONES IN THE MAINTENANCE OF CHEMICAL BALANCE

When an acute phase occurs in an endocrine disturbance, the underlying factor responsible for the critical or serious condition of the patient is usually a disturbance in his blood chemistry. The hormones were originally described or defined as chemical regulators by Claude Bernard in 1891. If we exclude the biological activity of the hormones on the tissue processes concerned in growth and sexual development and their respective physiological maintenance—however, even in these developmental processes, hormonal chemical processes and their regulation are operating as an essential factor—we must agree that the hormones most important in the maintenance of physiological balances are of chemical nature. It is of utmost importance to the therapist and also the diagnostician to recognize this fact. The therapist must promptly correct the abnormal chemical balance in the blood during an acute endocrine state by intravenous or a less rapid method of administration of the deficient blood chemical or chemicals, and then maintain the chemical balance at normal by administering the hormone or hormones which affect the metabolic control of these chemicals, and he must also exclude from the diet those foods which contain the chemical substances opposing the action of the deficient blood chemical and which have risen to above normal values during the deficiency period.

For example, the action of potassium in the body is opposed to that of sodium, and a similar relationship exists between phosphorus and calcium. Therefore, in endocrine disorders in which a deficiency of sodium or calcium occurs we eliminate, respectively, potassium or phosphorus. By recognizing the dietary factors of the disorder we not alone aid the patient's recovery and enhance his ability to establish normal blood chemical balance, but equally we diminish the requirements of hormone in the subsequent maintenance period. This principle of the reduction of the intake of foods containing the chemical that opposes the effect of the chemical found deficient in the endocrine disorder in question has been one of the great advancements in the management of endocrine disorders and

particularly of those cases in which there is a tendency for acute endocrine states to appear or recur

Now it may be asked "If the pituitary hormones, the adrenal cortical hormone, the androgens and the estrogens individually or collectively are concerned in maintaining the same single or combination of chemicals at normal levels in the blood, why, for example, do not all anterior pituitary deficiency states present in principle the abnormalities in blood chemistry observed in Simmonds' disease?" The explanation appears to be that Simmonds' disease represents a major deficiency in anterior pituitary function and that all other anterior pituitary deficiencies are less pronounced and thus do not present the same degree of disturbance in the interrelationships of the endocrine glands that is present in Simmonds' disease. The trophic factors of the anterior lobe normally stimulate the other members of the interrelated endocrinous system. In most instances of anterior pituitary deficiency one of the other endocrine glands takes on an increased role in the regulation of a chemical substance controlled by the anterior pituitary, thereby offsetting the effects of the primary anterior deficiency. In Simmonds' disease, however, we have essentially a "pan" deficiency of the trophic factors of the anterior lobe. The supplemental physiological activity of a gland (thyroid, adrenal cortex, gonads, parathyroid) associated in the control of the blood chemical becomes impossible because it is also atrophied along with the anterior lobe, and the deficiency of endocrine function is therefore a general one and on a parallel plane.

The same explanation may be offered for the infrequent acute episodes which occur in the more chronic or nonprogressive anterior pituitary deficiencies. For some unpredictable or unexplainable reason the supplemental augmented physiological activity of a cooperating hormonal mechanism may fail to maintain itself, and an acute phase occurs in an anterior pituitary deficiency disorder which usually seldom exhibits an acute or emergency state.

The extent of the chemical deficiency in the blood will naturally be directly proportionate to the degree of the deficiency of the one or more hormonal factors concerned in the blood chemical dysbalance. We are not alone combating a deficiency of an inorganic chemical such as sodium, chlorides or

calcium but a chemical dysbalance, for as the one inorganic chemical element in the blood falls in content its opposing inorganic chemical element rises in the blood. An exception is blood sugar (glucose), which is lowered as the result of a deficiency of the hormonal factors that bring it into the blood to offset the effect of insulin. The normal values of glucose in the blood are maintained by hormonal factors which are physiologically opposed. The pancreas produces insulin which consumes the glucose in the blood, thus lowering the blood sugar content. The lowering of the level of the blood sugar stimulates into activity those hormonal forces which mobilize blood sugar from the glucose storage depots, namely the diabetogenic factor of the anterior lobe, the adrenal cortical hormone, adrenalin from the adrenal medulla, and possibly pituitrin, and there is some evidence of an indirect action by the sex hormones. Co-operating with these hormonal mechanisms are nervous controls acting directly on sugar metabolism and indirectly through the endocrine mechanism. For these mechanisms to operate normally, liver function must be normal and muscular storage of glycogen must likewise be functioning.

HYPOGLYCEMIC CRISES IN ENDOCRINE DISORDERS

Disturbances of carbohydrate metabolism and blood sugar content account for most of the acute endocrine clinical states. Exclusive of diabetes, all of these acute conditions are associated with depressed blood sugar levels. The state of hypoglycemia may be due to a deficiency of function of either the anterior pituitary or of the adrenal cortex, or it may result from hyperinsulinism. In all cases it is the action of the insulin which produces the hypoglycemic state. In pituitary and adrenal cortical deficiency overproduction of insulin is not present, but normal insulin production by the pancreas is unopposed by the respective glands. In hyperinsulinism, a normal amount of blood sugar elevating fraction is being produced by the anterior pituitary and the adrenal cortex, but due to the presence of an adenoma of islet cells of the pancreas an increased amount of insulin is being produced and the blood sugar is reduced to sub-normal levels. It is therefore evident that with the finding of a low blood sugar or hypoglycemia we cannot arrive at a complete endocrine diagnosis or the method of therapy.

The diagnosis of hypoglycemia from the symptoms alone often presents difficulties. One has but to recall that most of the earliest cases of pancreatic adenomas were found in a mental hospital and that surgical extirpation of the adenoma cured these incorrectly diagnosed mental cases. This is one illustration of the necessity for the neurologist and psychiatrist to give a guarded diagnosis is the case of a mentally agitated patient whose mental episodes have been ushered in by an acute precipitant phase. Neurological manifestations in hypoglycemia may range from precipitant (no aura) convulsions or coma, attacks of amnesia or temporary disorientation, nervousness, restlessness, headaches and abnormal behaviorism, of unexplained origin, to complex syndromes of neuroagitated states with weakness and asthenia. Many hypoglycemic patients complain of sleeplessness and restlessness, palpitation, vague and widely diversified atypical pains, sweating, lack of concentration, temperamental outbursts, dizziness, swooning and mental lapses. In a measure the failure to explain the symptoms by any sound clinical interpretation should suggest the possibility of the presence of a hypoglycemic state, especially if the patient is to all outward appearances otherwise healthy in mind and body.

Unfortunately in hypoglycemia a low blood sugar level cannot always be demonstrated by a single sugar tolerance test or the four-hour curve. Very often it is necessary to make one or more six-hour curves to obtain an accurate hypoglycemic level. In other instances an insulin tolerance test is necessary to establish the insulin sensitivity of the patient. The insulin tolerance test is made by giving $\frac{1}{10}$ unit of insulin per kilogram of body weight. Whenever this test is given in a questionable case of Simmonds' disease, a 10 per cent glucose solution should be available for intravenous administration in the event a convulsion or coma is precipitated during the administration of the insulin.

The hypoglycemic patient may develop symptoms which are characteristic of the acute abdomen, particularly of appendicitis and gastric or duodenal ulcer which may even appear to be of the ruptured type. Gallbladder disease may also be simulated. One of our patients, a male aged eighteen years, had an emergency operation for appendicitis, and a normal appendix was removed. Six weeks later his symptoms were those of acute duodenal ulcer. The corrected diagnosis was eunuchoidism and

hypoglycemia Another patient, a woman aged twenty-four years with hypoglycemia, had a series of operations which started at age eighteen years with a dilatation and curettage for dysmenorrhea, which was followed at yearly intervals by appendectomy, thyroidectomy, oophorectomy, gastro-enterostomy, resection of gastro-enterostomy, cholecystostomy. None of these surgical procedures relieved her complex symptoms after the periods of postoperative care and recuperation had passed. During these periods her inactivity and dietary intake would adequately maintain her blood sugar. As soon as activity was resumed her carbohydrate metabolism again broke down and the symptom complexes which had simulated the accredited indications for her surgery recurred in part or in entirety. In fact the patient was referred to determine whether or not total castration was indicated. Her case illustrates the variety of surgical states under which hypoglycemia can masquerade and, more important, the unreliability of the four-hour sugar tolerance test even when repeated at frequent intervals. It required six-hour tolerance tests to demonstrate her hypoglycemic reactions.

Just as the patient with Addison's disease has an abnormal desire for salt and obtains a sense of improvement from its use, so does the hypoglycemic patient have an increased desire for sugar products, particularly within three hours after a meal or late at night. Likewise he obtains relief or amelioration of the acute or distressing symptoms following the ingestion of sugar. In other words, the diagnosis of the hypoglycemic state is initiated by the *history* of the patient. The importance of the history cannot be too forcefully stressed, as is well illustrated in the following case.

A male, aged thirty years, a recent college graduate and former college varsity football player, was diagnosed as having essential hypertension and diabetes. He complained of nervousness, palpitation, periods of weakness and exhaustion, profuse sweating, fatigue, falling asleep while reading a paper, in fact an almost constant tendency to drowse off during non-sleeping hours. He had changed, adversely, from a temperamental aspect. His mental output and energy were unfavorably affected. His physique and outward appearance was that of a varsity athlete. His complete physical examination had been reported to him as negative except for hyper-

tension, the blood pressure being 150 systolic and 90 diastolic, a sugar tolerance test of the diabetic type. He stated that he received a series of x-ray treatments to his adrenal gland for hypertension, a diabetic diet and 20 units of insulin daily. At end of two months his symptoms had not improved, in fact were aggravated and he was now unable to work because of pitation, nervousness, profuse sweating, weakness, somnolence, dizziness. Furthermore, he had become mentally morbid and his temperamental outbreaks and disinterest in home and the constant tendency to fall asleep made him intolerable to his recent bride.

The history of the patient, taken in detail prior to the aforementioned diagnosis, clearly revealed two facts: he had an abnormal desire for sugars, obtained temporary relief of his symptoms by ingestion of sugar and felt exceptionally well when alcoholic beverages were taken, and he had failed to gain weight in spite of discontinuance of training and varsity football. The immediate history revealed that his symptoms were aggravated in intensity, their complexity and duration were increased by the diabetic and insulin. In fact, he voluntarily discontinued insulin because of the reactions it induced and its intensification of his hunger for sweets with an inability to obtain the relief he formerly experienced. With a six-hour sugar tolerance test 60 mg. of sugar were found in the blood at two and four hours, and because of increasing symptoms of a hypoglycemic nature at the fifth hour glucose was orally administered and the symptoms relieved.

This patient when first examined was in an acute agitated mental state which could only be considered as being mixed with fears and despair. He was assured that he did not have diabetes and that his hypertension could be explained on the basis of a physiological reaction of the body to correct his hypoglycemia. With the proper dietary management, nourishment between meals, increasing the carbohydrate and fat content of his main meals and moderate exercise as walking after his evening meal, this patient promptly responded to his dietary therapy. Dietary management should first be explored before endocrine therapy is instituted. In this case a physiological adjustment has established itself without the aid of endocrine therapy.

The dietary habits of the hypoglycemic patient in respect to the desire for sugars and the temporary relief from eating sweets or drinking of alcohol and the onset of symptoms

one to four hours after meals keystone the structural diagnosis of hypoglycemia in the majority of cases. The symptom groups are so bizarre and mimic other previously mentioned organic disorders so closely that one cannot name any group of symptoms or single symptom as pathognomonic of the hypoglycemia. It matters not whether hypoglycemia is the only disorder or is part—and an important one—of Simmonds' disease or Addison's disease, it exists actively or potentially as an emergency or acute state to be reckoned with. This is well illustrated in the following case.

A woman, aged forty years, has had, for three years, a mild state of Addison's disease which was kept under control for eighteen recent months by the administration of 5 mg. of cortate every fifth day and increased salt intake. The patient was feeling so well that for the past few months she has discontinued routine injections of 5 mg. of cortate and has been taking the cortate only as symptoms of anorexia and "washed-out" sensations occurred.

For a period of four days this patient felt badly and remained in bed to "rest up." On the fifth day she awoke at 7 A.M. and complained of shortness of breath, dizziness and a feeling of faintness. She remained in bed and the symptoms disappeared but recurred one hour later. She arose at 8 20 A.M. for breakfast, twenty minutes later a convulsion occurred, this was succeeded by coma and she went into an extreme state of collapse with an imperceptible pulse and the blood pressure so low it could not be recorded. Ten milligrams of cortate was administered at 9 A.M. followed in ten minutes by 10 grains of caffeine-sodium benzoate and at 10 A.M. by 1 cc. of coramine. The patient remained in a critical state, the coma continued and the pulse became palpable but the blood pressure remained unrecordable. At 11 A.M. 5 grains of caffeine-sodium benzoate was administered and at 11 30 A.M. 1000 cc. of saline plus 10 per cent glucose and 1 cc. of adrenalin chloride 1:1000 was given intravenously and 5 mg. of cortate subcutaneously. The patient began to show improvement following administration of the intravenous glucose and saline and consciousness gradually returned. Ten hours after the onset of convulsions 700 cc. of saline plus 10 per cent glucose was given intravenously and this was followed one hour later by 5 mg. of cortate. The patient remained confined to bed for the following three days. Five milligrams of cortate was given twice daily and carbohydrate and salt intake was forced. During this period there was experienced a constant sensation as though there would be a return of symptoms. Improve-

ment continued and at the end of four days the cortate was reduced to a daily dose of 5 mg and eventually to a dose every third day. With this therapy the patient is now performing her normal duties.

Unfortunately no blood sugar or chloride studies could be obtained during the acute collapse of this patient, but not until the glucose and saline were administered was there any marked improvement in her condition in spite of the fact that the cardiovascular collapse appeared to dominate the clinical picture. The cardiovascular collapse appears to be secondary to the severe hypoglycemic state, since it was not found necessary to administer cardiac stimulants once the glucose and saline were administered.

This case clearly demonstrates the important aspects of blood chemistry in the acute phases of endocrine disturbances. While endocrine therapy is a requirement, we must recognize the fact that in such cases the hormone administered to correct the deficiency does not have the power to alter the blood chemistry speedily and the intravenous administration of the deficient chemical element must be utilized until the hormonal action of the administered hormone becomes effective. Cortate, which is desoxycorticosterone acetate, does not possess the positive action to raise the blood sugar, it thus differs from the adrenal cortical extract which has this quality to a better degree. The use of adrenal cortical extract is advised by Thorn in acute phases and in the crisis of Addison's disease. Thorn advises cortate later in the management of Addisonian crises.*

When adrenal cortical extract is not available and cortate is used, adrenalin chloride, 1 cc of 1:1000 solution, is a good therapeutic agent to elevate the blood sugar and also to support vascular tone. Unfortunately its use cannot be continued but it serves a useful purpose even though its elevating effect on the blood sugar is of short duration.

In Simmonds' disease one also observes similar acute episodes due to hypoglycemia, however, the patient usually lapses directly into coma, without convulsion preceding the comatose attack. This coma is always a critical state in Simmonds' disease, since the majority of cases terminate in coma. Within the pituitary

* Lukens, F. D. W. Disorders of the Adrenal Glands. *MED. CLIN. N. AM.*, 26:1810 (Nov.) 1942.

itary gland a progressive atrophy is occurring and gradually the patient enters a state in which the recoil powers within the endocrine system as a whole, with the exception of the pancreas, and the ability of the endocrine organs to support one another in opposing the action of insulin in lowering the blood sugar, is lost. The patient eventually arrives at a point where insulin is almost unopposed in its action, accordingly, in spite of all we employ by way of intravenous administration of glucose and adrenalin or the parenteral use of anterior pituitary and cortical extracts, a fatal outcome occurs. Neither of the adrenal preparations (cortical or medullary extract) can be repeatedly and indefinitely used for their blood sugar-raising properties without obtaining other major biological actions to an excessive and undesired degree.

The inability to offset therapeutically the collapse of the endocrine system in maintaining its role in elevating blood sugar has been experienced in other types of pituitary and adrenal gland disease.

One case was that of a male, aged sixty-two years, who had a pituitary cyst. The cyst was apparently a degenerative process of an eosinophilic tumor of the anterior lobe, since the patient exhibited a *formes frustes* type of acromegaly. The patient had been actively engaged as a farmer and experienced no clinical symptoms until three days prior to the acute onset of his illness and death. He first complained of headache and later dizziness and weakness but still continued to work in the fields. He suddenly lapsed into coma in the late afternoon and was admitted to the hospital in coma and cardiovascular collapse. Blood chemical studies revealed a severe hypoglycemia and low blood chlorides and sodium.

For a period of three days the patient received glucose and saline intravenously, adrenal cortical extract, adrenalin and the usual supportive treatment for cardiovascular collapse. He would regain consciousness after receiving glucose and saline intravenously but gradually the blood sugar would again fail and coma and collapse recur, whereupon intravenous glucose and saline would be readministered. This state of reaction and collapse continued until death ensued. The futility of therapy in this case was explained by the autopsy. The cyst of the pituitary comprised all but 10 per cent of the anterior lobe. The histological study of this structure showed that it consisted mainly of atrophic anterior pituitary cells. The adrenal glands were extensively atrophied and the cortex was ex-

tremely thin The histological study of the adrenal cortex also revealed atrophic and degenerative changes.

The adrenal cortex unquestionably plays a stellar role in maintaining blood sugar levels It may be either secondarily involved as in the previous case or primarily involved as in Addison's disease and the following case

The patient, a woman aged sixty-three years, had had comparatively good health prior to her present acute attack Before the breakfast hour she experienced dizziness and nausea, suddenly collapsed and lapsed into coma She also exhibited the usual signs of cardiovascular collapse The blood sugar level in this patient was so low that it could not be determined accurately and it was recorded as below 20 on three different occasions The administration of intravenous glucose did not materially alter the pretherapeutic recorded values The patient failed to respond to glucose and saline administration and supplemental therapy and death occurred forty-eight hours after the onset of her coma.

The autopsy revealed an extensive and generalized hemorrhage in both adrenal glands The cortical area was practically disrupted by the violence of the hemorrhage Again in this case the futility of corrective therapy is evident

This condition occurs more commonly in young infants than in adults and has been termed the *Waterhouse-Friderichsen syndrome* In the *Lancet*, June 26, 1943, Morison reviewed the literature of bilateral adrenal hemorrhage and reported three more cases occurring in infants In most cases this condition in infancy is associated with an infectious process and he recommends, beside hormones and supportive treatment, the administration of plasma

It should not be assumed because of such fatal cases that therapy should not be energetically and rationally pursued in cases of endocrine disease with severe hypoglycemic episodes Many endocrine patients who experience convulsions and coma due to hypoglycemic attacks recover spontaneously Such attacks occur most frequently in cases of *advanced hypogonadism* and in *eunuchoidism* In the majority of instances these patients have the convulsive seizures in the early morning hours It is known that in normal individuals the blood sugar reaches its lowest level at from 4 to 5 A.M. The attacks may also occur after fasting or excessive fatigue

Patients with hypogonadism, in fact those with any anterior

pituitary deficiency and in some instances those with hypothyroid deficiency, may exhibit what is spoken of as an insulin sensitivity or a tendency to experience hypoglycemic attacks. It can readily be seen why such patients have attacks in the early morning when the blood sugar is normally at its lowest. These attacks may occur before breakfast or with fasting for a sugar tolerance test.

Of course, nervousness and emotional upsets predispose such patients to these attacks, because of the increased utilization of carbohydrates at such periods. The management of the cases of these young hypogonadal patients is exceedingly complex. The requirements of growth and development take much of their ingested food energy and it is difficult in some instances to obtain sufficient positive carbohydrate reserves by forced feedings during the non-sleeping hours to prevent the early morning seizures. In these cases it has been found necessary to awaken the patient at midnight and give him an 8- to 12-oz. feeding of two parts milk, one part cream to which one or two level tablespoonfuls of sugar of milk is added.

These patients eventually overcome their insulin sensitivity if normal puberty and adolescence eventuates. It is my personal opinion that in young hypogonads the oral administration of anterior pituitary and thyroid stimulates gonadal development. This therapy has been fully discussed by the author previously.* The administration of male hormone in such cases is, we believe, undesirable. Our observations show masturbation has increased the frequency of convulsive attacks in these cases after male hormone therapy. The danger of exciting penile response and a desire for masturbation outweighs the positive metabolic balance secured by the administration of male hormone.

It must be realized that young hypoglycemic patients must have their blood sugar maintained at a normal level over the twenty-four-hour period and for a period of months until gonadal normalcy is established. Consequently our endocrine therapy must be of a kind that will be effective and tolerated for a long time. There is no evidence at hand indicating that male hormone therapy with the possible exception of implant therapy will stimulate testicular development. This inability of male

* Dunn, C. W., *Diagnosis and Treatment of Testicular Deficiency—Male Hormone Therapy* MED CLIN N AM., 26 1867 (Nov) 1942

hormone to stimulate gonadal development we hold to be another reason against the use of male hormone in youthful hypogonadal cases. It is very evident from our studies of adult eunuchoidism that the hypogonadism is a factor in insulin sensitivity since all other anterior pituitary factors appear to be in adequate function. It cannot be definitely stated, however, that the factor of carbohydrate intake is exclusively at fault in the adolescent or adult eunuchoid with hypoglycemia.

It is known that the hypogonadal patient has a negative nitrogen balance and that the administration of male hormone creates a positive nitrogen balance and weight gain. The benefit the adult hypogonad with hypoglycemia obtains from male hormone we believe results from the carbohydrates indirectly derived from his improved protein metabolism. More important is the fact that this carbohydrate derived from protein becomes available during the latter period of absorption of the food intake and at the time he most requires it for sustaining his blood sugar until the next meal period.

The necessity for carbohydrates in the management of the thyroid crises and in the preoperative care of acute toxic hyperthyroidism is generally accepted. If the carbohydrate and chloride content of the blood is disregarded, the patient suffers or is unfortunately sacrificed during the initial management of the crises.

The subject of hypoglycemia has been discussed at some length because it does appear from our experience to be involved in the majority of acute endocrine states with the one exception of hypoparathyroidism.

HYPOPARATHYROIDISM

One of the occasional postoperative events in hyperthyroid patients whose toxic state requires an extensive excision of the lateral lobe is that more than one parathyroid gland is unintentionally excised and shortly thereafter parathyroid tetany develops, in a few cases a tetanic convulsion appears without forewarning. In most instances the patient presents a warning that a hypoparathyroid state is developing by complaining of cramps or stiffness in the legs, difficulty in swallowing or tightness of the facial or cervical muscles. Examination at this time will show the presence of either the Trousseau or Chvostek sign,

or both, a lowering of blood calcium, and an elevation of blood phosphorus. One cannot be certain from the level of the blood calcium as to the seriousness of the condition because some patients will experience tetanic convulsion when the blood calcium levels have reached 8.5 mg. per 100 cc. of blood, while others will not have a convulsive seizure until the blood calcium level reaches just above 6 mg. of calcium per 100 cc. of blood. In view of this it appears advisable to proceed on the basis that every patient with hypoparathyroidism must have his blood calcium brought to normal as quickly as possible.

For a period of time, even though we had available the parathyroid hormone, the treatment of hypoparathyroidism was unsatisfactory. Early management consisted in the administration in the acute phase of from 300 to 500 units of parathyroid hormone and the intravenous administration of calcium. Later, oral administration of calcium was substituted for the intravenous method and the patient was given 100 or more units of parathyroid hormone per diem. At the end of two or three months, however, the patient became insensitive to the parathyroid hormone.

To offset the failure of parathyroid hormone to act, large doses of viosterol were then given to facilitate the absorption of calcium. It is the metabolism and absorption of calcium which is defective in hypoparathyroidism, thus, merely increasing the amount of orally administered calcium is ineffective. Another therapeutic agent used was thyroid extract. Thyroid extract will mobilize calcium from its storage depots. Here it must be pointed out that in the case of the toxic thyroid of some duration the hyperthyroidism has quite naturally depleted the calcium stores and in some cases of hyperthyroidism osteoporosis occurs.

The therapeutic dilemma of chronic hypoparathyroidism appears to have been solved with the discovery of A.T. 10 marketed in this country under the name of *Hytakerol* (Winthrop). This is a 0.5 per cent solution of dihydrotachysterol in oil and 1 cc. represents 5 mg. of dihydrotachysterol. This preparation is potent in raising the level of blood calcium, in fact, its dosage must be closely checked with blood calcium studies beginning forty-eight hours after its initial administration which is exclusively by the oral method.

The dosage of A T 10 or dihydrotachysterol is from 3 to 10 cc daily for the first forty-eight hours, in the meantime clinical symptoms are controlled by the intravenous administration of calcium gluconate in doses of 5 to 10 cc of 10 per cent or 20 per cent neo-calglucon or another suitable calcium salt

Large doses of calcium gluconate or lactate, 10 to 15 gm, are administered orally As soon as the blood calcium level rises to 9.5 or 10 mg and there is an accompanying fall in the blood phosphorus, the dosage of A T 10 is reduced at least 50 per cent from its previous level A state of hyperglycemia can be quickly produced by the unnecessarily prolonged use of A.T. 10, accordingly, its dosage is regulated to keep blood calcium at from 9.5 to 10 mg per 100 cc of blood

Fortunately, many patients with hypoparathyroidism develop spontaneous cures This is believed to result from the physiological hyperplasia of the remaining parathyroid glands, as a response to the body's demand for more parathyroid hormone Thus it is desirable to encourage this physiological demand on parathyroid tissue by maintaining the dosage of A T 10 at the least required level as soon as the emergency state is passed.

The management of hypoparathyroidism therefore consists in energetic treatment during the emergency period and then gradual reduction of therapy to establish whenever possible a spontaneous cure If spontaneous cure of the hypoparathyroidism does not take place the patient must be continued on a low phosphorus diet which should be instituted as soon as practicable after the acute tetanic period has passed, and in addition, he should be given A T 10 at a dosage rate that will maintain the blood calcium between 9.5 and 10.5 mg per 100 cc of blood The treated patient must also be watched during observation for the appearance of cataract, since therapy does not prevent the occurrence of cataracts of the eye

The action of A T 10 on the blood calcium has certain sustaining qualities which permit the patient to be treated by weekly doses of from 1 to 7 cc after the maintenance level has been established Dosages in all stages of hypoparathyroidism are based on the individual requirements of the patient, and consist of that amount required for the relief of symptoms and the elevation of the blood calcium to normal range in the acute

stage, and of that amount required for maintaining the blood calcium at a normal level later. A simple, practical method for determining the approximate level of blood calcium can be utilized, namely the *Sulkowitch test*. The Sulkowitch reagent when mixed with an equal part of urine acts upon its calcium. A negative reaction indicates the absence of calcium in the urine, a low blood calcium and the necessity of increasing the dose of A.T. 10 in order to prevent or relieve symptoms. A fine white cloud in the test tube indicates a normal blood calcium level and that the dosage of hytakerol is adequate, the test should be repeated within a short time, however, in order that the cumulative action of A.T. 10 may be avoided. Excessive dosage is indicated by the formation of a milklike precipitate and under such circumstances the dosage should be immediately reduced or temporarily discontinued and the blood calcium is checked. The treated patient showing this type of test is bordering on a hypercalcemic state and may be evincing early signs of toxicity.

The symptoms of *hypercalcemia* which usually appear when the blood calcium reaches 15 to 16 mg. per 100 cc. of blood are anorexia, nausea and vomiting associated with languor in the initial stages. If corrective measures such as confinement to bed, increased fluid intake, increased elimination and light diet along with regulation of therapy are not then instituted, the patient may quickly pass into a more toxic state, evidenced by headache, vertigo, abdominal cramps, thirst, polyuria, ataxia of the lower extremities and stupor. The seriousness of the above symptoms is apparent and the urgency of active elimination therapy as well as discontinuance of treatment is apparent.

In Addison's disease a similar chemical toxic state has been induced by the too liberal use of cortical extract and desoxycorticosterone acetate (cortate). In this circumstance the sodium and chloride of the blood reach abnormal levels, and as a result the body retains too much fluid and this in turn causes edema particularly of the extremities, and enlargement of the heart because of increased blood volume. This latter factor has resulted in a fatal issue, accordingly, whenever an adrenal cortical hormone preparation is used one must make sure that the blood chlorides do not rise above normal values. The treatment of

hyperchloremia consists in the release of blood volume in cases with acute cardiac signs, stoppage of therapy, increased elimination, restricted salt and light diet

SUICIDAL TENDENCIES IN SEVERE MIGRAINE AND HYPOGONADISM

Severe depression and melancholia leading to suicidal acts are more frequent than are commonly supposed in endocrine disorders and particularly is this true in adult hypogonadism, the climacteric and severe migraine

Every case of migraine which does not definitely respond to psychotherapy, to dietetic therapy, or the various migraine remedies, including ergotamine tartrate and histamine desensitization, should be treated with a series of large doses (10,000 to 30,000 R U) of estradiol benzoate, administered every forty-eight to seventy-two hours and even daily if the severity of symptoms fills the patient with despair and gives rise to suicidal intentions. Estradiol benzoate in a dosage lower than 10,000 R U and in some cases even 20,000 R U will aggravate the severe migraine attacks, producing violent, persistent cephalgia, intense nausea and sometimes vomiting. The physical prostration and mental reactions of the patient are similarly unfavorably affected by small doses.

Quite frequently in the more severe cases which do not respond to the previously mentioned high dosage of estradiol benzoate, as high as 80,000 R U of estradiol preparations must be administered. They are usually administered as 30,000 R U of estradiol benzoate and 2.5 mg or 5 mg of estradiol dipropionate. Since these patients are in a severe depressed state because they have not responded to the usual forms of therapy for migraine they frequently contemplate suicide, and one can never be too certain that they will not attempt it.

Lest it be felt that we are exaggerating the degree of mental disease and the suicidal tendencies in severe migraine and hypogonadism the following case history is submitted.

The patient, a male aged thirty-four years, three years ago became worried and depressed. He conceived the idea that neighbors and friends believed him to be a homosexual because he avoided all feminine contacts. To relieve his mental reactions he periodically resorted to excessive alcohol. During these periods of intoxication

he became resistive and assaultive. He had been confined to a mental hospital on two occasions, the second because he attempted to hang himself by his belt during a depressed period. Shortly thereafter he was submitted for endocrinological survey which determined the presence of a distinct gonadal deficiency, he was therefore given 25 mg of Oreton three times a week. He stated that after 150 mg of Oreton had been administered he experienced an improvement and in view of this improvement the therapy was continued and he was again paroled. Treatment was discontinued, he again became depressed, began to drink and was again mindful of the alleged homosexual insinuations. He was readmitted and shortly thereafter given an implant of 300 mg of testosterone. Under this regimen the patient returned to normal and resumed his occupation. He received an implant of 300 mg of testosterone once every three or four months.

The patient's improvement persisted until September, 1942, when he required another 300-mg implant, but owing to discontinuance of the manufacture of pellet implants it was possible to give him an implant containing only 150 mg of testosterone. He was not advised of the reduction in dosage. In three weeks he returned and complained that he had not responded. He was then given 50 mg of Oreton by hypodermic. He was quite discouraged by the results of the implant and four weeks later was given another 150-mg implant, again without advising him of the reduction in dosage. Within a short time it was necessary to administer Oreton, 50 mg hypodermically, to relieve his depressed state. He gained the conception that his condition was becoming worse because implants did not relieve him and the hypodermics of Oreton were not as effective as the implant.

In February, 1943, it became necessary to advise the patient that the dosage of the implant had been reduced and that implants were no longer available, after the one then to be administered. He received the third implant of 150 mg of testosterone on February 20. He stated that if this did not relieve him he did not know what he could do. He was requested to report on February 27, 1943. He was definitely convinced that the implant therapy had maintained him in a normal state for a period of two years while 300 mg of testosterone was being used. This was substantiated by clinical observations, behavior and employment, and records of the case. Hypodermic injections, though improving his condition, were associated with cycles of improvement and waning effect which made him unstable, as opposed to the feeling of stability and well being given by the 300-mg implant. On February 26,

1943, this patient, who during the period of observation had been cooperative and considerate and patient, placed himself in the bathtub and sent a well directed shot through his brain to end for all time the mental despair and depression which his hyposexuality produced. His lack of desire to "make a mess" and consideration of others remained with him to the end, and a useful war worker was lost because of unavailable therapy.

From this case, other reported cases and personal observations of hyposexuality, one can only be cautious of the patients' intentions once they intimate that they consider suicide, or attempt it.

SUMMARY

In summary, therefore, we are faced with the fact that there do exist acute episodes in endocrine disturbances. In the main they are of major proportions and in a number of instances they have a fatal outcome naturally or violently.

These patients suffer from a deficiency which is of a chemical nature. The chemicals may be inorganic and nonendocrinous, or organic and endocrinous. During the acute stage of the illness it is necessary to remedy as quickly as possible both phases of this chemical deficiency. During the period of intensive treatment and maintenance therapy it is always necessary to bear in mind that an exaggerated physiological or toxic state may be induced and this in turn may necessitate emergency treatment.

PSYCHOSOMATIC ASPECTS OF MEDICAL PRACTICE IN WARTIME

EDWARD WEISS M.D., F.A.C.P.*

It is generally acknowledged that about one third of the patients who consult the average physician have no definite bodily disease to account for their illness. In wartime this figure is probably somewhat increased.¹ In a recent study of 200 consecutive patients classified as follows: (1) those in whom the illness seemed to depend entirely on emotional problems, (2) those in whom the illness seemed in part dependent on emotional problems, and (3) those in whom an emotional problem did not seem to enter into the cause of the illness, 35 per cent were placed in the first group, 35 per cent in the second, and 30 in the last.

How should the physician deal with these patients? How should they be studied and how treated? It is the purpose of this clinic to discuss these questions briefly.

Quite commonly such patients are told that there is no evidence of organic disease, that the trouble is "functional," and they are dismissed without further attention only to land eventually in the care of some irregular practitioner or quack healer. Worse than that, the physician sometimes takes the attitude that the illness is imaginary, or that the patient is malingering, or he may assume that in some vague way the patient is deliberately responsible for the illness, refers to him as a "damn neurotic," and gives him the kind of care that must necessarily go with such a characterization. The patient may also be told that the physician does not *think* anything is the matter, but suspicion is cast upon some organ or system which needs watching and care. This happens very frequently with regard to the symptom of fatigue and the suspicion of pulmonary tuberculosis and often results in a state of chronic invalidism. Lastly, following thorough study by means of medical history, physical

* Professor of Clinical Medicine, Temple University Medical School

examination and laboratory investigation, some pathologic curiosity* may be discovered which really has nothing to do with the illness. The patient is then treated as though organically diseased and is submitted to unnecessary medical or surgical treatment which, in many instances, intensifies the neurotic condition.

EMOTIONAL PROBLEMS

What is the matter with these patients and how should they be treated? They are suffering from disturbances in their emotional lives, that is, the illness is of psychologic origin and can be satisfactorily studied and treated only from the psychologic standpoint. In civil life the ill health arises in a predisposed individual because of longstanding dissatisfaction in the business, social, or home life. The stresses of war impose further burdens upon such predisposed persons. This failure of adjustment to environment is manifested by a disturbance in some part of the personality, either as bodily symptoms of various kinds, capable of mimicking almost any disease, or as affections of the spirit resulting in attacks of anxiety, obsessions, phobias, depression, and other disturbances of mood.

Why is it that so many physicians are unwilling to admit the psychologic basis for such illnesses, or if they do grudgingly concede that "a nervous factor is present," they believe it to be of secondary importance and probably the result of physical disease? In discussing a case of this kind they are apt to say, "but there must be something the matter," meaning that there must be a physical basis for the illness and that if they are just thorough enough in their investigation, "something" will be found. However, long-time follow-up studies on such patients fail to indicate that organic disease develops in any significant number, even when it does, we must not forget that a neurotic patient may develop an organic disease that is unrelated to his neurosis just as he similarly runs a chance of getting hit by a motor car.

Every physician freely acknowledges the relation of psychic causes to such physiologic phenomena as blushing, weeping,

* By "pathologic curiosity" is meant some congenital or acquired lesion that has no significance from the standpoint of health. Slight deviations of the nasal septum and calcified primary tuberculous lesions in the lung are examples.

goose flesh, and even on occasions to vomiting, diarrhea and so forth, but many, nevertheless, find it difficult to believe that more prolonged (chronic) disturbances of a physiologic nature can possibly be psychogenic in origin. This is due to the structural and physiologic training of modern medicine and came about in the following fashion

THE ORGANIC TRADITION IN MEDICINE

The physician of ancient times was concerned with the spiritual basis of illness, but the structural concept introduced by Virchow led to the separation of illness from the psyche of man and a consideration of disease as only a disorder of organs and cells. With this separation of disease into many different ailments came the development of specialists to attend to all of these distinct diseases. With the specialists came the introduction of instruments of precision, and the mechanization of medicine began. Medicine now contented itself with the study of the organism as a physiologic mechanism, impressed by blood chemistry, electrocardiography, etc., but unimpressed and, indeed, often holding in contempt the investigation of the life situation of the individual, which was not considered as scientific as the results of laboratory studies. This period may in truth be referred to as the machine age in medicine. It is not to be denied that remarkable developments have occurred during this period of laboratory ascendancy, but it also must be admitted that the emotional side of illness has been almost entirely neglected.

As a consequence of this structural and physiological tradition in medicine and lack of training in psychosomatic medicine, a great many physicians pride themselves upon their unwillingness to concede the absence of physical disease when dealing with an obscure illness. This failure to recognize neurosis and treatment of the patient as organically diseased happens most frequently, as already suggested, because modern clinical medicine attempts to establish the diagnosis of a functional disorder by ruling out organic disease through medical history, physical examination, and laboratory investigation. The point that I particularly wish to make is that the diagnosis of functional illness must be established not simply by exclusion of organic disease but on its own characteristics as well. Neurosis should be a positive as well as a negative diagnosis. In other words, neurosis

has its own distinctive features to be discovered by a study of the emotional life. Only in this way can serious errors in diagnosis and treatment be avoided. If this statement is admitted, it must naturally follow that personality study is just as important in the problem of chronic illness as laboratory investigation.

PSYCHOSOMATIC STUDY IN CHRONIC ILLNESS

Now the question is—how do we proceed with this kind of a study? For general purposes it may be stated that in addition to the physical study it consists in simply getting to know the patient as a human being rather than only as a medical case. Too often, as already stated, the patient is looked upon only as a physiologic mechanism and is studied by means of medical history and physical examinations aided by “instruments of precision” and chemical tests. Tape measures and test tube carry the erroneous notion of exactness and thoroughness—erroneous because the emotional life of the individual, which may hold the key to the solution of the problem, is not investigated or at best inadequately so.

In regard to the latter point, too many physicians feel that they have done their duty to the study of the emotional life if they ask the patient if he is worried about anything and receive a negative reply. They are the same physicians who are apt to remark about a patient “but he doesn’t look neurotic,” perhaps believing that such a patient should by his general apprehension or by evidences of physical nervousness betray the fact that he is neurotic. Unfortunately, most neurotics do not betray any neurosis in their appearance, nor is the approach to their emotional problem so simple that the direct question—“Are you worried about anything?”—will produce information of importance. Probably the best way to deal with these patients is first to satisfy ourselves and establish their confidence by a thorough medical history, physical examination, and such laboratory tests as are necessary to exclude organic disease.² Having assured the patient that no physical disease is present, it is usually easy, by means of examples of psychic causes for such physiologic disturbances as blushing, goose flesh, palpitation and diarrhea, to make the patient understand that a disturbance in his emotional life may be responsible for the symptoms. The important clues to this disturbance can usually be found by

encouraging a discussion of problems centering around vocational, religious, marital and parent-child relationships. This is usually best accomplished indirectly rather than by direct questions. In the case of adults, domestic problems and professional and business relationships play a large part in functional illness. In young unmarried people, family relationships, the choice of a career, and often religious and sexual problems are important for discussion. War problems, of course, concern both.

THE CIVIL APPLICATION OF MILITARY EXPERIENCE

In these days when there are so few physicians left to carry on civil practice it is, of course, necessary for them to do their work in the shortest possible time. Obviously this will not permit a lengthy interview for many patients but a way must be found to provide time for the few who really need it. Experience gained in induction board work provides a clue in this regard because there an immense number of men have to be examined in a very short time. Hence the neuropsychiatrists have worked out a system to screen out the maladjusted. One such technic, as employed at the Boston Induction Station,⁸ is employed during the neurological part of the examination and afterwards, when questions are asked in about the following words: "How is your general health? Have you ever been seriously sick? Any bad accidents? Have you ever been knocked out? Do you ever have headaches? Dizzy spells? Fits or convulsions of any kind? Any stomach trouble? Nervous trouble? Have you ever had a nervous breakdown? Has anyone in your family ever had one? Or any of the other things I've just asked you about? How old are you? What work do you do? What before that? What's the longest job you've held? How far did you go in school? How much do you drink? Have you ever been arrested? What do you think about going into the Army?" Or with a volunteer, "Why are you joining the Army?"

Of course, depending on the answers, other questions are asked—for example, "How old when you quit school? How many grades did you have to repeat?" or, "How much time have you lost from work in the past year on account of sickness?" And where mental deficiency is suspected on the basis of school and individual history, and, still more, on the basis of response to questions, directions and general attitude, "How

much is a half of a half? What year is this? Why it is called that? Why does the sun rise in the morning and set in the night?" Those men at marginal level are referred to the psychometrist for examination. His report is added to the work-sheet and the man comes back to the referring psychiatrist who makes the final decision as to acceptance or rejection.

The authors go on to say "As has been noted, examinations have been carried out by many different examiners. Two facts emerged very quickly. First, a neuropsychiatrist of clinical experience, thrust into this situation, presented with the problem and the general knowledge roughly of the criteria of acceptance, quickly worked out a technic of examination which satisfied him. It is extremely interesting that the technic evolved by so many different men was so nearly similar—a fact suggesting that the solution to the problem was probably fairly correct, since it was independently arrived at by many different examiners. It is of further interest that numerous published reports from centers all over the country describe remarkably similar technics of examination. The second point was the remarkable uniformity of rejection rate of the examiners with the greatest clinical experience. This figure ranges from 6 per cent to 9 per cent. Some examiners averaged as low as 1 per cent, some as high as 16 per cent. When one considers the clinical background of the various examiners, it seems reasonable to assume that the true incidence of rejectable defects discoverable in such an examination as this is somewhere in the neighborhood of 7½ per cent, and that those examiners whose rejection rate was consistently much lower were failing to find pathology, or had too lenient a standard."

BODY LANGUAGE

I often tell my patients that if they cannot find an outlet for tension of emotional origin by word or action, the body will find a means of expressing this tension through a kind of "body language." For example, if a patient cannot swallow satisfactorily and no organic cause can be found, it may mean that there is something in the life situation of the patient that he "cannot swallow." Nausea in the absence of organic disease sometimes means that the patient "cannot stomach" this or that environmental factor. Frequently a feeling of chest oppression accompanied by sighing respirations, again in the absence of

organic findings, indicates that the patient has a "load on his chest" that he would like to get rid of by talking about his problems. This kind of an explanation applies to a great variety of symptoms and often appeals to the patient as a common-sense approach to the emotional factor in illness. Again and again it has permitted me to understand something about the life situation of the patient.

SEXUAL FACTORS

This is too large a subject to cover in a short paper, but one point of special importance does deserve consideration and that is the relation of sexuality to neurosis. Ever since the introduction of the epoch-making studies of Freud to the problems of neurosis, medicine has misunderstood his conception of sexuality. He has often been quoted to the effect that disturbances in genital activity are the sole cause of the neuroses. This is quite far from the truth. It is rather that difficulty in the sexual sphere appears as a revealing index to a neurotic personality and can be looked upon in that light. In other words, in much the same manner that urea retention serves as an index to an impending uremia so do disturbances in the sexual life of the individual, such as varying degrees of frigidity in the female and varying degrees of impotence in the male, serve as a reliable index to the kind of a personality that is very liable to develop a neurosis.

APPLICATION OF FINDINGS

Many physicians will ask "Well, suppose you do find something of importance in the emotional life of the patient, some conflict that is causing illness, what can you do about it? What good does it do the patient to know?" First of all, it is often a great help to the patient to know that the ailment is not organic in origin but is due to a disturbance in his emotional life. It gives him a great deal of reassurance and is the first step in the right direction. When a symptom is divorced from the fear of organic disease, cancer, for example, it becomes easier for the patient to tolerate the symptom and, surprisingly enough it may, and often does, disappear. Secondly, such knowledge and such an approach will frequently save the patient unnecessary, troublesome and expensive medical or surgical treatment with a resulting further degree of invalidism.

Often just the talking out of the problem with the physician will alleviate symptoms, and frequently some simple adjustment will accomplish real help. This caution must be sounded, however, it is a good rule for the physician to listen rather than talk, giving advice on important emotional matters is dangerous. For just as there is major and minor surgery, so there exist major and minor forms of psychotherapy, and while the average physician should not attempt major forms of psychotherapy, he must be able to recognize the severe neuroses so that he may refer them elsewhere for treatment. He should be able to deal with the simpler neuroses not only for the purpose of helping such patients in a positive way but also to save them from unnecessary medical and surgical treatment and exploitation by quacks and irregular practitioners.

EPIDEMIC KERATOCONJUNCTIVITIS*

ALSON E. BRALEY M D †

IN 1941 a severe form of acute conjunctivitis appeared in the shipbuilding plants of San Francisco. It spread quickly through several industrial plants and to the civilian population. This epidemic disease received considerable publicity and came to be known as "shipyard conjunctivitis" or "California conjunctivitis." Since its inception in California the disease spread quickly to the East coast and thence toward the South and Midwest. Because the names "California conjunctivitis" and "shipyard conjunctivitis" were not considered descriptive, the name "epidemic keratoconjunctivitis" was suggested and quickly adopted. Apparently the disease was present in California before it reached epidemic proportions in San Francisco because Hobson¹ in 1938 reported sixteen cases of a superficial punctate keratitis from a veterans' hospital in San Fernando, California. From his reports it appears that most of these might have been similar to those later reported by Rieke,² de Roeth,³ and Hogan and Crawford⁴ as epidemic keratoconjunctivitis.

Similar diseases have been reported under several different names. In 1889 Fuchs⁵ observed in an epidemic thirty-eight cases of a disease he called "superficial punctate keratitis." The keratitis was preceded by an acute conjunctivitis. A close similarity is noted between the disease he described and the present disease. In his description, he stated that it was a form of superficial keratitis related to herpes febrilis corneae but not associated with the formation of vesicles. These corneal changes had a predilection for the superficial layers and were concentrated in the central portions of the cornea. He also emphasized

*From the Department of Ophthalmology, College of Physicians and Surgeons, Columbia University, and the Institute of Ophthalmology of Presbyterian Hospital, New York City.

† Assistant Professor, Department of Ophthalmology, College of Physicians and Surgeons, Columbia University, and Assistant Attending Surgeon, Vanderbilt Clinic and Presbyterian Hospital, New York City.

that the disease was frequently unilateral and that following the recovery from the acute conjunctivitis, pain, photophobia and lacrimation were common. Reports by Adler,⁶ Von Reuss⁷ and others indicate that there must have been an epidemic of the disease in Vienna in 1889.

A similar disease was reported in 1900 by Herbert⁸ who observed twenty-six cases in Bombay. The disease must have become endemic since no further reports of the disease appeared until 1920 when Kirkpatrick⁹ made a short report of a similar disease. Then Wright¹⁰ and later Kirwin¹¹ described extensive epidemics in Madras, India. It would seem from these reports that the disease must have been fairly widespread in India between 1920 and 1933. Outbreaks of a similar disease occurred in India and China from 1933 to 1936, in Germany again from 1938 to 1940 and in Malaya from 1935 to 1938. Hamilton¹² in discussing a survey of eye diseases in Tasmania, described numerous cases similar to our present disease. Holmes¹³ in 1941 reported 10,000 cases in Oahu, Hawaii. From these findings, it would seem that the disease was epidemic in the Near East and East Indian islands. Some of the cases reported, however, are not identical with the disease as I have seen it but certainly there were a large number of cases in that area before the disease appeared on our West coast. It seems possible that the present epidemic may have begun in Malaya, spread to Hawaii and then to our West coast.

It is difficult to determine just how many cases have occurred in the United States since 1941. Whenever an epidemic occurs, it is always possible that a large number of cases of other types of conjunctivitis may be mistaken for the epidemic disease. I have observed over 2000 cases from the New York area. If this area represents approximately 10 per cent of the total population of the United States, then there may well have been 20,000 cases in the entire population.

THE CLINICAL DISEASE

In order to present a clinical picture of the disease the following case is cited:

Mr. R. H. had been followed in the Vanderbilt Clinic for five years because of a chronic glaucoma. He was a night clerk in a small New York hotel and came in contact with many people. His

conjunctiva and cornea had always been normal and the tension was controlled with 2 per cent pilocarpine

In June of 1942, Mr R. H. appeared at the Vanderbilt Clinic with a history that the previous night he had felt a sudden sharp pain in his right eye. This was associated with a marked foreign body sensation. He was unable to find a foreign body but the sensation and occasional sharp pains continued. By the following morning he had considerable edema of the upper lid and it was difficult for him to open his eye. The foreign body sensation still persisted and there was moderate pain and discomfort in the eye, especially on movement of the eyeball. Vision in the eye was normal. There was considerable edema of the right upper lid and moderate chemosis was present. The conjunctiva was smooth, the blood vessels distended. There was edema of the semilunar fold and caruncle but little edema of the lower lid. A preauricular lymph node was not palpable. Cultures from the conjunctiva grew diphtheroids and a few colonies of *Staphylococcus aureus*. Scrapings from the conjunctiva showed epithelial cells with numerous mononuclear leukocytes, no polymorphonuclear leukocytes were found.

By the second day the edema had increased somewhat. The conjunctiva showed numerous follicles on the lower lid and a few follicles on the lateral margins of the tarsus of the upper lid. The edema of the caruncle and semilunar fold was more marked and there was a painful, slightly tender preauricular lymph node. He stated that he had a slight head cold and some headache. His temperature was 98.6° F. He complained of an occasional foreign body sensation in the left eye.

During the next five days the clinical findings gradually increased until he was unable to keep his right eye open. Photophobia was not marked. On the fifth day the edema was decreasing and the preauricular lymph node was smaller and less tender. However, submental and submaxillary lymph nodes were present. On the sixth day the patient noted moderate photophobia for the first time. A few fine subepithelial opacities were seen in the cornea with the slit lamp. The cornea did not stain with fluorescein. The edema of the left eye had increased but was not as severe as it had been in the right eye. There was also a preauricular lymph node on the left side.

On the eighth day the conjunctivitis in the right eye had improved but the photophobia was more marked and numerous half-millimeter whitish opacities could be seen in the cornea. These opacities were just beneath the epithelium and although the epithelium seemed slightly raised over some, they did not stain with fluorescein. Approximately thirty opacities were counted in the

central portion of the cornea and all of them seemed to be localized in or slightly superficial to Bowman's membrane. The opacities were circular and composed of numerous fine dots, when viewed with the high power of the slit lamp. The preauricular lymph node was just palpable. Vision in this eye had decreased to 20/70. Although the acute conjunctivitis in the left eye was decreasing, a few corneal opacities were also present.

The acute conjunctivitis lasted four weeks in each eye, seeming to improve rather slowly during the last week but the visual disturbance and corneal changes persisted. Photophobia was still present, especially marked in artificial light. Six months later the vision in the right eye had improved to 20/30 and numerous subepithelial corneal opacities were present. In the left eye there were a few corneal opacities and the vision was not disturbed. These corneal opacities seemed to have become thinner. They were circular and composed of numerous fine dots but the number of dots present in the individual opacities seemed to decrease gradually. One year later, the right cornea showed eight opacities while the left eye had two. No scars were present from previous opacities. The vision in the right eye was 20/30 and photophobia in artificial light was mild.

From this case and many concurrent cases a light of clinical findings present themselves. The most common early symptoms are *foreign body sensation* associated with pain and lacrimation. The *edema* of the upper lid, bulbar conjunctiva, caruncle and semilunar fold are striking. This is associated with or followed by a *follicular conjunctivitis* accompanied by preauricular lymphadenopathy. *Tearing* is marked but purulent discharge is rare. The lids feel sticky and scratchy but are not stuck shut as is so frequent in acute bacterial conjunctivitis.

Frequently *small hemorrhages* are seen on both the bulbar and palpebral conjunctiva but these are not as severe as frequently seen in acute pneumococcal conjunctivitis. The more severe cases many times develop a *pseudomembrane* on the lower palpebral conjunctival surface. This pseudomembrane is thin when compared to the thick pseudomembrane of a streptococcal conjunctivitis, but much thicker than the very fine pseudomembrane associated with allergic conjunctivitis. A membrane may also be present on the upper lid. A pseudomembrane was present on the third to fifth day in 67 per cent of the cases. The pseudomembrane when examined microscopically was composed almost entirely of epithelial cells with mononuclear cells scat-

tered throughout. When the pseudomembrane is light yellow in color it contains many more mononuclear cells and degenerating epithelial cells. This was usually present on the fifth to the seventh day. Early the slightly opaque translucent membrane is composed almost entirely of viable superficial conjunctival cells. I was unable to demonstrate virus bodies (inclusion bodies) in any appreciable number although when the membrane is stained by the Giemsa method an occasional blue staining body could be seen in the cytoplasm. Victoria blue stain failed to demonstrate any virus.

The typical *subcorneal infiltrations* usually develop on the eighth or ninth day of the disease but they may develop as early as the fourth day or as late as the twenty-first day.

EARLY DIAGNOSIS

The diagnosis of epidemic keratoconjunctivitis during the early stages before the development of the typical corneal opacities, is difficult. A common styne near the outer angle of the upper lid will give rise to considerable edema with a large preauricular lymph node and occasionally a few follicles on the conjunctiva. The styne of course becomes apparent in a few days. Nearly any of the acute bacterial types of conjunctivitis may be associated with edema, a preauricular lymph node and to a lesser extent, follicles. However, in nearly all acute bacterial conjunctivitides, the polymorphonuclear leukocytes are predominant in the conjunctival secretion.

The early diagnosis of epidemic conjunctivitis then is dependent upon acute symptoms with or without preauricular lymphadenopathy and the finding of large numbers of mononuclear leukocytes in the conjunctival secretion. Here again, however, one disease which also has a tendency to run in epidemic form, called "Beal's conjunctivitis," shows only mononuclears in secretion smears. The early diagnosis is then based on clinical impressions and laboratory findings before the corneal infiltrates develop. It is not possible to use the preauricular lymph node as a criterion in differential diagnosis, since it may be enlarged in other diseases as well. I have seen a number of typical cases of epidemic keratoconjunctivitis that did not show a palpable preauricular lymph node when examined. Some of the cases observed from the onset of the disease showed only

a transient preauricular lymphadenopathy The lymph node was palpable during the first or second day of the disease and disappearing thereafter In some cases, however, the lymphadenopathy persisted for months after the acute conjunctival symptoms had subsided

ETIOLOGY

A good deal of material for experimental use was obtained from Mr R H This material was given to Dr Murray Sanders who succeeded in isolating a filtrable virus Doctor Sanders placed the scrapings from the conjunctiva into fluid tissue cultures, which were allowed to stand at room temperature The infected tissue cultures were ground and inoculated intracerebrally, intraperitoneally and intravenously into young 10- to 12-gm white mice The mice developed encephalitis in from three to five days, which when passed to other mice or back to tissue culture, finally became a potent virus Blood serum from the patient neutralized the virus obtained by Doctor Sanders He was able to isolate a similar virus from other sources and found that patients recovering from epidemic conjunctivitis had serum antibodies* to his virus If Doctor Sanders¹⁴ work is confirmed by other investigators, then there is little doubt that the disease is due to a filtrable virus The fact that patients recovering from the disease carry immune bodies in their serum may indicate that they are probably immune to further attacks of the disease

EPIDEMIOLOGY

The epidemiology of an outbreak of epidemic keratoconjunctivitis from the Schenectady, New York, area was reported by Perkins, Korns and Westphal¹⁵ Their reports are of a great deal of interest The acute conjunctivitis in their series was bilateral in 56 per cent of the cases, corneal opacities developed in 85.5 per cent of which 28.4 per cent were bilateral The corneal opacities occurred from the seventh to the twenty-third day in 92 per cent of the cases and the clearing-up of the opacities was slow In their series they noted that the highest incidence of infection occurred in the dispensary These authors were unable to demonstrate any definite relationship between the dispensary and the individual cases of epidemic keratocon-

* The word "antibodies" is used advisedly for want of a better term I mean the substance in the plasma which neutralizes the virus

junctivitis but it seemed to be suggested that the dispensary was the important place of the transmission of the disease. In a study conducted recently by Sanders, Gulliver, Forcheimer and Alexander¹⁰ it was suggested from the charts that individuals obtained their infections in a physician's office.

From my own experience a number of individuals have contracted epidemic keratoconjunctivitis in periods from five to fourteen days after being exposed to a case in the clinic. Two patients are of interest.

An attending ophthalmologist at Vanderbilt Clinic was demonstrating cases of conjunctivitis to a group of medical students. One case was an early epidemic keratoconjunctivitis, the diagnosis of which was somewhat obscure. Five days after demonstrating this case, he noted a foreign body sensation in his left eye with considerable discomfort, especially on rotation of the globe. The symptoms gradually became worse until there was considerable chemosis and edema of the upper lid. He followed the usual course of the disease with the disease becoming bilateral on the third day after the first eye had become involved. Corneal opacities developed in the left eye on the eighth day and a few in the other eye on the twelfth day.

The original patient demonstrated, had a more virulent infection as judged by the amount of edema and conjunctival reaction but the number of corneal opacities in both were approximately the same. The husband of the patient demonstrated by the physician also developed epidemic keratoconjunctivitis.

One case has been called to my attention in which the tonometer used for measuring intraocular pressure may have transmitted the disease to a second patient. Although the clinics and dispensaries are being incriminated as the source of transmission, a great many patients have been seen who had not had any previous contact with either a physician's office or a clinic. There may be a mild upper respiratory infection associated with the disease. In crowded places it is not unlikely that droplet eye infections may occur. With this thought in mind, two other patients are of interest.

Miss N was an operating room nurse in a large local hospital. She came in contact with very few people. On her day off she went on a shopping tour and visited several large department stores.

To her knowledge, she did not encounter anyone with acute conjunctivitis. One week after her tour she developed acute conjunctivitis in her left eye which became a typical epidemic keratoconjunctivitis.

Miss C P was a director of occupational therapy in a large hospital for chronic diseases and her directing duties were such that she rarely came in contact with anyone except the personnel of her department. She made a train trip and likewise did not knowingly come in contact with any cases of acute conjunctivitis but eight days later developed an acute case of what subsequently proved to be epidemic keratoconjunctivitis.

These cases illustrate the possibility of infection either by fomites or droplets from individuals who may or may not have the disease. Both of these infections occurred during the time the disease was quite widespread in the city.

It would appear from these findings that the disease is quite contagious. However, during the study of the epidemic in the Schenectady area, approximately six physicians examined the patients without contracting the disease. The only care observed was that of washing one's hands after each examination.

The only possible conclusion to be drawn from the epidemiological studies is that the disease may be transmitted from one individual to another either by direct transmission or by a third party. I was told by one physician that he probably transmitted the disease to two of his patients before he was aware that he had the disease. The studies of Sanders, Gulliver and associates¹⁶ seem to indicate that the ophthalmologist may have transmitted the infection in the cases they studied. The second possibility of fomite or droplet infection from individuals without the disease is much more remote.

The possibility of *corneal foreign bodies* contributing to the transmission of the disease has been considered. In a number of cases seen at the Vanderbilt Clinic, a few gave the history of a corneal foreign body. From the records of the clinic three cases have been chosen whose histories are so similar that a summary of one will be sufficient.

Mr P was a hospital employee who got something in his left eye on his way to work. He reported to the Vanderbilt Clinic and under pontocaine anesthesia a small foreign body was removed.

from his cornea without much difficulty Sulfathiazole was placed in the eye and the eye covered The following morning the corneal abrasion had healed and the eye looked normal Six days later, he again returned with an acute conjunctivitis and a tentative diagnosis of epidemic keratoconjunctivitis was made This was subsequently confirmed when the typical corneal changes occurred

There is little doubt in my mind that he was inoculated with epidemic keratoconjunctivitis when the corneal foreign body was removed. There is a possibility that the foreign particle may have carried the infection into the eye However, during the period of the epidemic, comparatively few cases with corneal foreign bodies developed the disease

RESULTS OF THERAPY

At the present writing, 229 cases have had controlled treatment Of this number, the majority were treated with either 5 per cent sulfathiazole ointment or 0.25 per cent pontocaine and 1:2000 adrenalin The patients received considerable symptomatic relief from the use of a local anesthetic and a vasoconstrictor The 5 per cent sulfathiazole ointment seemed to make most of them more uncomfortable and did not shorten the course of the disease Local 2 per cent penicillin was used in three cases without beneficial effect Ten cases were treated with sulfathiazole sesquihydrate without any appreciable effect To date five cases have been treated with 20 mg per cent tyrothricin, which, when freshly made, seems to decrease the severity of the acute conjunctivitis but does not prevent the formation of the corneal opacities.

Since individuals recovering from epidemic keratoconjunctivitis develop immune bodies to the virus, *convalescent serum* and later *plasma* were obtained and given to patients with early epidemic keratoconjunctivitis The antibody titer of the convalescents was checked at intervals and when this titer was highest, blood was withdrawn and processed by Dr John Scudder and his group Fifty cubic centimeters of convalescent plasma were then injected intravenously into patients suffering from epidemic keratoconjunctivitis on the second to fourteenth day of the disease In the first group of ten patients there was one failure¹⁷ In the next ten, three failures were encountered Of the three failures, two individuals had already developed

corneal opacities while the other received the plasma on the seventh day of the disease and developed opacities on the following day. The primary criteria used in evaluating the treatment was the development of the corneal opacities. Since a positive diagnosis could not be made without the typical corneal opacities, all treated patients were checked periodically to determine the antibody titer of their serum. All individuals, whether considered as successes or failures, developed antibodies. Since it is possible that the convalescent serum may stimulate the formation of antibodies, five patients with purulent conjunctivitis were given convalescent plasma and none of these patients developed antibodies to the virus isolated by Doctor Sanders.

From the results of therapy it will be seen that the only substance in my hands that has been successful in preventing the development of corneal opacities has been convalescent plasma. From this small series of twenty cases, it would appear that the convalescent plasma must be given early, preferably before the third day and not later than the fifth day of the disease. The majority of the patients experienced a sense of complete symptomatic relief during the first forty-eight hours after receiving convalescent plasma.

SUMMARY

- 1 Diseases similar to epidemic keratoconjunctivitis have been reported at intervals since 1889.
- 2 It is probable that our present epidemic began in Malaya in 1938 from whence it spread to Hawaii and the continental United States.
- 3 The clinical features of the disease consist of edema, lymphoid hyperplasia, enlarged preauricular lymph node, marked tearing with no purulent discharge and the typical subepithelial infiltrations.
- 4 The cause is probably a filtrable virus.
- 5 Patients recovering from the disease have immune bodies to the virus in their serum.
- 6 Epidemiology is obscure but certainly in a few epidemics the physician was responsible for the transmission of the disease. Simple hygienic measures, chiefly cleanliness of the hands, seem to prevent transmission.
- 7 Convalescent plasma seems to be the treatment of choice.

A THERAPEUTIC EVALUATION OF BENZEDRINE SULFATE IN THE TREATMENT OF SEASICKNESS RESULTS IN 100 CASES

FREDERICK K. ALBRECHT, M.D.*
United States Public Health Service

SEASICKNESS has been widely discussed and with diversity of opinion as to its cause, but no treatment has as yet been perfected on a rational basis. The rolling and pitching of ships causes unusual stimulation of the semicircular canals as a result of the continuous movement of endolymph and irritation of the receptors. Predisposing causes are poor ventilation, unpleasant odors of a ship's hold, constipation, migraine, disturbances of orientation, vagotonia, gastro-intestinal disturbances, and psychic impressions as seen in those who become seasick before the vessel sails, or from seeing and hearing the distress of others who are ill.

Abnormal conditions induced by unusual movements are not limited to man. Seasickness has been noted in horses, dogs, cattle and sheep. It is stated that women and neurotics are unusually susceptible to seasickness. Racial differences have been described in the literature, and in my own experience Filipinos and Puerto Ricans were noted to be very susceptible. Deaf-mutes and those in whom the vestibular apparatus is destroyed are free from vertigo by virtue of labyrinthine aplasia. Children accustomed to spinning, infants, and the aged are relatively immune to seasickness.

The most seasoned passenger or crew member may develop seasickness. Lord Nelson, the hero of many British naval battles is said to have been seasick most of the time. Different vessels have their peculiarities of roll and pitch and a seasoned sailor on one ship may become violently ill on another ship, or a passenger during his first sea voyage may escape seasickness only to be stricken on a subsequent voyage. Some sailors acquire their "sea legs" soon while others, like the writer, never acquire them.

* Passed Assistant Surgeon, U S Marine Hospital, Baltimore, Maryland

SYMPTOMS AND SIGNS

The basic symptoms are anorexia to food, salivation, cold sweats, pallor, vertigo, headache, nausea, vomiting and retching. Intestinal spasm may cause severe cramps, and diarrhea, palpitation and collapse may also be a part of the clinical picture.

Hill of the Aquitania has classified the symptoms as referable to the sympathetic and parasympathetic nervous systems.

Symptoms	<i>Vagotonia</i> (More common in men)	<i>Sympatheticotonia</i> (More common in women)
Nausea	Variable	Constant
Vomiting	Absent or only at long intervals	Frequently repeated
Relief of nausea following emesis	Usually marked	Slight or transient
Headache	Early, persistent, often occipital or vertical	Late if present and usually frontal
Vertigo	Early	Late
Pulse rate	60 or less	80 or higher
Blood pressure	Low	High

Hill attempted to separate the symptoms for the purpose of treatment, but there is usually a crossing of the characteristics in the same case and no two cases are exactly similar. I became acutely aware of this subject while acting as Medical Officer aboard a Coast Guard cutter in the Caribbean Area during 1941-42. The 100 cases reported upon here represent for the most part U S Coastguardsmen stationed at Puerto Rico, St. Thomas, Virgin Islands, Miami, Florida, and Key West, Florida.

For some reason seamen greatly dislike to admit being seasick, and when forced to come to the sick bay, they will deny seasickness but will complain of other ailments ranging from low back pain to headache in the hope that they will be put on the sick list and be allowed to stay in their bunks. Just why being seasick should be considered a disgrace is not entirely clear when we realize that some folks have been going to sea all their lives and have never been able to be entirely free of this malady. Instead of "kidding" these patients and thereby destroying the rapport between doctor and patient, I have found that by confessing my own inadequacy at sea, the most hardened seaman after some hesitation will readily admit that seasickness is also his chief difficulty. These persons suffer much at times from abuse heaped upon them by fellow crew members. It is un-

fortunate that not too many officers can be found aboard ships whose sympathy and understanding encompasses such "trivial" matters as seasickness. Some of these patients develop a psychoneurosis, others attempt or contemplate "jumping ship," and I recall a few cases of attempted suicide due to a feeling of inadequacy aggravated by the torments of fellow crew members.

RESULTS IN 100 CASES OF SEASICKNESS TREATED WITH BENZEDRINE SULFATE

This study presents the results achieved on 100 patients, seventeen of whom were women of whom the majority were from service families returning to the mainland of the United States. Most of them were well traveled and had been to sea many times. The balance of the group consisted mainly of Coast guardsmen, as previously mentioned.

CLINICAL PICTURE IN 100 CASES OF SEASICKNESS

Age of Patients

Varied from 17 to 42 years

Duration of Symptoms

20 years	1 per cent
7 years	1 " "
5 years	4 " "
3 years	8 " "
1 year	20 " "
6 months to 1 year	28 " "
Less than 6 months	38 " "

Symptoms

Nausea	91 per cent
Vomiting	80 " "
Headache	86 " "
Occipital	10 per cent
Vertical	50 " "
Frontal	12 " "
Generalized	14 " "
Salivation	34 " "
Sweating	36 " "
Prostration	13 " "
Anorexia	80 " "
Refused all food	29 per cent
Only liquids tolerated	16 " "
Food tolerated only in recumbent position	3 " "
Mild, variable, only in rough water	32 " "
Vertigo	50 " "

Other Features

Previous neurotic history (2 cases were failures)	4 per cent
Previous history of gastro intestinal disorders (6 were failures, 4 of whom were chronic alcoholics)	10 " "
Previous air or car sickness (3 failures)	14 " "

FOLLOWING ADMINISTRATION OF THE DRUG

Symptoms

Xerostomia	11 per cent
Insomnia	2 "
Euphoria	8 " "
Rash	2 " "
	(Questionable)
Habituation	0 " "
Palpitation	0 " "
Irritability	1 "

Failures

Complete (Men, 15 per cent women, 3 per cent)	18 per cent
Equivocal (Men 1 per cent women, 3 per cent)	4 "
<i>Complete Relief of Symptoms</i>	78 per cent

Comment

The dosage of the drug varied from 15 to 30 mg daily, and in all cases it was given in divided doses. It was found that in many cases where the patient had arisen from the recumbent position, once he assumed the erect position and the swaying motion of the vessel had caused the chain of symptoms to begin, emesis would prevent the ingestion of the drug. Accordingly, in almost all cases where practicable, the drug was advised to be taken from five to ten minutes before the patient arose from his or her bunk. All cases were carefully controlled using placebos which had the same form and taste as the original benzedrine sulfate tablet. In the overwhelming majority of cases, when the drug was replaced with the placebo most of the symptoms returned, and when the drug was again given the patient all troublesome symptoms disappeared and the patients were able to resume activity, enjoy walking about the deck and eating without any difficulty. Some of the U S Coastguardsmen patients had been going to sea for from five to twenty years and had never known complete relief before in rough water until

taking benzedrine. In some the symptoms were not severe enough to cause them to lay off duty but they were unable to eat and were not able to do efficient work. As a result they were frequent callers at the sick bay and some were even sent to hospitals for the treatment of migraine and gastro-enteritis.

Complete Relief of Symptoms—In 26 per cent of the total group, complete amelioration of symptoms was secured by the administration of 10 mg. of the drug before arising and 5 mg. twice daily. A striking improvement was noted in these patients. The Coastguardsmen were able to eat, stand their watches in all sorts of weather and their morale improved greatly with their increased tolerance to the pitching and rolling of the vessel. Stewards who formerly became sick at the sight and smell of food during rough weather were able to carry on their duties without difficulty. Firemen and oilers who were made ill by both the motion of the vessel and the smell of Diesel oil were able to work without further nausea, vomiting, or anorexia.

Another group of twenty-five patients (25 per cent) noted symptoms only in very rough weather. They were unable to carry on their duties but received some relief from assuming the recumbent position. Complete relief of all symptoms followed the use of benzedrine and they were able to carry on their duties in all weather.

The remainder (27 per cent) of the patients securing complete relief from benzedrine were those who became violently ill in mild weather or from even a slight rolling motion of the ship. While all received complete relief from the drug, an immediate return of the symptoms was noted upon the administration of placebos.

Two patients were in the third, one in the fourth, and one in the sixth month of pregnancy. All were violently ill and received complete relief of symptoms from 10 mg. of benzedrine three times daily.

Failures—Of the failures (22 per cent), six gave a previous gastro-intestinal history of gastric upsets and of these six, four were chronic alcoholics. Six other failures were considered neurotic either by a previous history or by observation. Three other failures gave a history of previous car or airsickness.

Blood Pressure—It was possible to check the blood pressures in only 71 per cent of these cases. In no case was there an appreciable rise in either the systolic or the diastolic pressure.

In 6 per cent there was a drop of from 5 to 7 mm of mercury in the systolic pressure

Loss of Weight—Thirty-four per cent of the patients reported a loss of weight, in some cases ranging from 8 to 20 pounds, before taking benzedrine. In *all* cases, the patients were able to resume eating and gained back all the weight lost. Before taking benzedrine, the writer lost 14 pounds per week while at sea in rough weather. Atropine and several antispasmodics and sedatives were tried to no avail, but following the administration of benzedrine sulfate, 20 mg daily, he regained his normal weight.

Habituation—In no case was there any sign of habituation, nor was there any increased tolerance to the drug noted. In fact, in many cases it was possible to decrease the dosage of the drug, but it is noteworthy that where this was possible and placebos were given, all or many of the symptoms returned promptly.

Other Features—Xerostomia was present in 11 per cent of the cases but in no case was it troublesome, it was relieved by chewing gum. The two cases of rash which occurred were questionable in that both patients had eaten sea food for which there was a definite allergic history. Euphoria was noted particularly in those cases in which the patient drank much strong black coffee (aptly called "boiler compound" by seamen) in order to keep awake on long watches. While anxiety was present in some of the failures, since it had been present before the drug was given we did not consider the drug as a factor in its etiology.

SUMMARY

One hundred cases of seasickness are described with symptoms before and after receiving benzedrine sulfate. All cases were carefully controlled. This study, limited as it is, suggests that benzedrine given in proper dosage and under the supervision of a doctor (not entirely necessary) is a safe drug for the prophylaxis of seasickness. Its use permits the patient to be up and about and to partake of his usual nourishment. There are no distressing drug symptoms and no evidences of habituation. This drug might well be used by our armed forces to good advantage. None will deny that a seasick soldier or sailor is of little help to himself or to others, in fact, he is a distinct liability as he requires attention from other personnel who might

be better employed at the time. In the case of members of the armed forces unaccustomed to sea travel who are enroute to the theater of operations or are engaged in landing operations, the drug would not only prevent a great percentage of seasickness in those susceptible, but it would also provide a possible beneficial psychomotor stimulus as well.

BILIARY DRAINAGE BY DUODENAL INTUBATION*

WILLIAM DALE BEAMER M.D.†

PAST and present experience with upper intestinal intubation renders it desirable to reevaluate our ability to make adequate examinations of the biliary tract by collection of bile from the duodenum. Certainly the procedure as commonly practiced by those not thoroughly indoctrinated in the use of the duodenal tube often leads to inconclusive results, when but little basic knowledge is necessary for correct interpretation of the findings. It is my purpose here to review the principles and to recognize those factors which produce unsatisfactory results.

HISTORY OF DUODENAL INTUBATION

The use of a mechanical device to empty the gastro-intestinal tract was initiated by Kussmaul, who first practiced gastric lavage in 1867.¹ The first serious attempt to enter the duodenum came twenty-eight years later when Hemmeter² used a combination of two tubes. On the distal end of one tube was a balloon grooved on its upper surface when inflated in the stomach. The groove was designed to act as a guide for the entrance of the second tube into the pyloric canal. Obviously such an arrangement, although ingenious, could not be practical because of the difficulty and often impossibility of placing the distal end of the groove opposite the pylorus. Kuhn³ in 1898 attempted to improve upon this by inserting a wire spiral in an ordinary stomach tube, and by patient and painstaking manipulation to insert it into the duodenum. Thus matters stood until 1909 when Linhorn⁴ developed a small bore, soft rubber tube which ended in a perforated metal capsule. The tube was found to be generally useful for aspirating either gastric or duodenal contents.

* From the Department of Physiology and the Gastro-enterological Section of the Department of Medicine, Jefferson Medical College, Philadelphia.

† Ross V. Patterson Fellow in Physiology and Gastro-enterology, Jefferson Medical College.

or for tubal feedings into either the stomach or duodenum Rehfuß in his recent book⁶ describes the development of his tip in 1912 Gross,⁵ Palefski,⁷ Levin,⁸ Lyon⁸ and others devised modified tips also, but such improvements did little to revive the lagging interest in biliary drainage. The necessary stimulus was provided by Lyon¹⁰ in 1919, who made successful clinical application of the idea after having read a footnote in a paper by Meltzer¹¹ two and a half years previously, suggesting that 25 cc of 25 per cent magnesium sulfate would relax the sphincter of Oddi as well as the duodenal wall and permit the bile to flow. Although based upon a "law of reciprocal innervation," for which evidence is lacking (cf. Ivy's review¹²), there is little doubt of normal relationship between relaxation of the sphincter of Oddi and increased gallbladder pressure not necessarily dependent on nerve pathways. However, this does not minimize the great step forward. Since that time there has been no especial improvement either in the technic of duodenal intubation or in methods of obtaining a dependable flow of bile. The studies have mainly been confined to learning which substances are most potent in their cholagogue effect.

TECHNIC OF PASSING THE TUBE

Confidence on the part of the operator is a definite prerequisite for successful passage of the tube. The patient must be put completely at ease. Time spent in first explaining and reassuring him may spell the difference between successful drainage of the gallbladder and failure. If there is likelihood of nausea, the throat may be painted with 1 per cent nupercaine solution, but in so doing the patient must be forewarned of the drying and numbing effect since its unexpected occurrence may make him more apprehensive. As the tube is swallowed, gagging may occur in spite of carefully repeated instructions. Without raising the voice, the operator directs the patient to cease swallowing and take several deep breaths of air through his wide-open mouth. The head must never be thrown back, but must be maintained in a normal position at all times. If, in spite of all precautions, revulsion occurs after two or three attempts, the patient should be sent home with instructions to take a sedative before retiring. The next morning the procedure may be repeated, and it is probable that with time to review his part and

with inhibitions lowered by the sedative he may be able to carry out the intubation without difficulty

When the tube reaches the lower pole of the stomach, usually at the 56-cm. mark, 8 ounces of warm water or saline are introduced through a funnel, and withdrawn immediately by gravity siphonage. Difficulty of entrance and evacuation of the solution may indicate that cardiospasm has prevented the tip of the tube from entering the stomach. This may be overcome by a few minutes' distraction, such as reading a newspaper or walking about. It is inadvisable to attempt complete recovery of the solution or to lavage further, since time spent here is unnecessary and is tiring to the patient. The tube may be clamped off or left open. The patient lies on his right side with his shoulder low and hips elevated so that the heavy tip will gravitate to the pylorus. He is then instructed to swallow easily at intervals so that at least twenty minutes are consumed in permitting the tube to advance 20 cm. At the same time, for psychic stimulation of peristaltic activity, he may imagine he is digesting some favorite food. Aaron¹⁸ suggests pressure or percussion over the fifth dorsal vertebra, and tapotement (a tapping motion of the fingers on the epigastrium by rapid supination of the hands when the hypothenar eminences rest upon the abdomen), or the application of Credé's method of placental delivery to the stomach. Any of these methods may be useful in causing a stubborn pyloric sphincter to open. The patient should not be hurt or unduly excited, since any unexpected action may cause the stomach to relax.⁶ A temporary change of position, even walking about, may permit the tip to enter the duodenum.

The correct position of the tip in the duodenum is best determined by fluoroscopy, but when this is not available a flow of viscid yellow bile is good evidence. A flow of turbid bile or of the neutral or alkaline contents means that the tip is in the duodenum but that it may still be in the cap, proximal to the ampulla of Vater, or may even have reached the jejunum. Auscultation upon injecting air is helpful but not too exact. There is no sure way of checking the position except by roentgen examination. The mere presence of bile should not be misleading. It is easily regurgitated into the stomach, but here the bile salts are precipitated and a sediment appears in place of the viscid material previously mentioned.

Care must still be exercised to prevent regurgitation of the tip into the stomach, which may occur from restlessness of the patient or, more frequently, with nausea due to retrograde movements of the duodenum which push the tip in a proximal rather than a distal direction¹⁴ The patient should not talk during the entire procedure because of the nauseating effect of the tube in the throat A difference of opinion exists, however, and some may encourage the patient to talk to increase his confidence

Nevertheless, at this point particularly he should be oblivious to his surroundings and may sleep, read or listen to the radio It is advisable not to keep the patient intubated longer than necessary

OBTAINING THE SPECIMENS

The physiology of the mechanism for emptying the gallbladder has been studied extensively but still is imperfectly understood That the closing and opening of the sphincter of Oddi (the existence of which is now generally agreed upon) is important, is seen in all experimental studies on the pressures exerted by the secreting liver, gallbladder and the various ducts^{16, 17}

Direct relaxation of the sphincter of Oddi seems of value, and *nitroglycerin*^{18, 20, 26} has frequently been suggested for this purpose In my experience, however, this drug is inconsistent in reducing the spasm of the sphincter and too often permits the tip of the tube to fall back into the stomach, therefore I have discontinued its use

Pavatrime (B-diethylaminoethyl fluorene-9-carboxylate hydrochloride) in doses of 360 mg has yielded fairly good results It is believed to relax the duodenum and sphincter of Oddi When introduced through the tube into the duodenum there is usually a quiescent period of fifteen to twenty-five minutes, after which the "B" bile makes an abrupt appearance The color changes in the bile are gradual, the most intense golden brown occurring about twenty-five minutes after the first flow When the administration of the drug is successful the resultant formation of a fluorescent turbid yellow solution in the alkaline duodenum is apt to be confusing in the first collections of bile When pavatrime has not induced a flow of bile I have found that a magnesium sulfate-peptone solution seldom is effective either

In dogs the response to pavatrine is not the same as in the human subject. In ten experiments¹⁸ a flow of bile was noted in only two, amounting to no more than 15 cc in either case, and the bile was not concentrated.

So far the substance found most effective in emptying the gallbladder is a mixture of *cream and egg yolk*, the stimulating effect depending on the fat content.²¹ This does not excite the duodenum as much as olive oil— but has the disadvantage in common with all other media of mixing with the samples of bile.

In order to avoid contamination, I have allowed the tube to progress to the third portion of the duodenum or into the jejunum, introduced the stimulant followed by a little air, and then have withdrawn the tube until the tip reached the middle of the descending portion of the duodenum. The substances apparently act as well from the jejunum as from above, but it is not always possible to encourage the longer journey of the tube.

The next most effective substance is a solution of 5 or 10 per cent *peptone*. I have used *Bacto-protone* (a mixture of proteoses) in the same strength and prefer it, as with this preparation there is usually sharper delineation and more rapid collection of the gallbladder bile than with peptone. In controlled experiments on dogs having duodenal cannulas, a flow of concentrated gallbladder bile occurred within five minutes after installing 25 cc of 5 per cent *Bacto-protone* into either the duodenum or jejunum. Twenty-four experiments were performed with only one failure.¹⁹ Two dogs were used in four additional experiments. One had a bisected loop of jejunum and an intact nervous system except for the divided myenteric plexus, the other had an intestinal anastomosis just above an ileal fistula, and was vagotomized and splanchnicectomized. The proteose solution was perfused through the loop and fistula. The latter animal gave no response to the stimulus while the former yielded a flow of bile similar in all respects to that of normal dogs. This could suggest that the stimulus is carried by way of extrinsic reflex pathways, but it may indicate simply that the ileum is incapable of cooperation. It is said that cholecystokinin is generated in the duodenum.

In the Curtis Clinic, we use a solution consisting of 20 cc of 7 per cent *peptone* and 10 cc of 50 per cent *magnesium sulfate*

with successful drainages in about 70 per cent of all cases. The magnesium sulfate tends to relax the sphincter of Oddi (but may fail if used alone^{15, 21}) and the peptone is presumed to cause the gallbladder to contract. The completeness of evacuation is always questionable unless a dye-filled gallbladder is visualized by roentgen examination before and afterward. I am quite sure that it rarely empties completely.

SOME FACTORS INVOLVED IN EMPTYING

It appears important that the intubation should be begun early in the morning, since there is a psychophysical disturbance with increased duodenal irritability in most individuals whose breakfast is delayed. To effect a satisfactory drainage it is also important that the gallbladder be well filled, as it normally is after a twelve-hour fast. A full gallbladder exerts an increased pressure to insure a flow of bile. One should not be misled into wrong diagnosis on the basis of absence of gallbladder bile when the organ has not had a sufficient length of time in which to store up bile. The pressure of the bile in a well-filled gallbladder may influence its tone. A high tonus may be just as important in maintaining a sufficient pressure within the gallbladder as active contraction of the musculature during the emptying process. At any rate, Bainbridge and Dale²³ found that distention augmented tonus rhythm without causing contraction in anesthetized dogs, and Ivy¹² has never seen a good contraction in dogs in the digestive state with a partially emptied or contracted gallbladder. In addition, Deissler and Higgins²⁷ found that a certain optimum pressure was necessary in guinea pigs' gallbladders to produce normal tonus rhythm and that higher pressures would overcome the resistance of the sphincter of Oddi with leakage of the fluid.

Although the gallbladder is rather well supplied with fine nerve fibers and ganglia, present-day evidence suggests that these may exert a regulatory influence on tonus rather than initiate gallbladder contraction. That such tonus changes may be carried by nerve pathways would seem to be true from the experience of Boyden and Parmacek,²⁴ who frequently obtained a slight flow of bile on mere perception of fried bacon, or the observation of Levene²⁵ of a sudden increase in the size of the gallbladder during nausea.

We note that upon stimulation we do not always obtain a response in increased bile flow even when the gallbladder is fairly well filled. We may deduce that such a failure may be due to a low intraluminal pressure^{12 27} which makes a stimulus ineffectual when it would be adequate if the tone level were higher. Of course it may be due to abnormal spasticity of the sphincter of Oddi. Because of this we should not be hasty in drawing the conclusion that there is obstruction due to other causes when we do not obtain a flow of bile.

EXAMINING THE BILE

Students always ask, "What should we look for?" The normal *color sequence* of the biliary drainage is *prima facie* evidence of a normally functioning biliary tract. The consensus among gastroenterologists is that the dark "B" bile comes only from the gallbladder. One may obtain a concentrated bile upon occasion in a cholecystectomized patient, but this would argue for a compensatory condition which is desirable. When "B" bile is present in only small amounts and with a relatively low concentration, it may be assumed that the gallbladder is functioning poorly. Complete absence of "B" bile is indicative of a blocked or non-functioning gallbladder. Absence of "A," "B" and "C" fractions must be due to complete closure of the common bile duct. Except in the last case, no one attempt is sufficiently conclusive for diagnosis. The degree of clarity or turbidity of the fraction is somewhat indicative of the state of the organs.

Microscopic examination only elaborates the picture of the color sequence. It reflects the condition of the part from which the bile originated. The examiner looks first for those particles usually present in disease of that part of the gall tract. The key to the anatomical structure from which the bile was obtained is in the type of desquamated epithelial cell which he views under the microscope, for example, the tall columnar cells which line the gallbladder serve as a check on the accuracy of recognizing "B" bile as coming from that structure. He further looks for pus, blood and crystals, especially cholesterol and calcium bilirubinate. In studying the pus cells, he notes whether they are bile-stained and whether they are degenerate, as these are clues to the extent of disease and the degree of stasis. He also examines the contents for parasites and bacteria,

making cultures in any uncertain case. In this latter connection, I might add that after careful mouth cleansing and with sterile apparatus the chances of obtaining an accurate culture are fairly good. When the same growth is found in two or three subsequent drainages and associated with other indications of infection, the evidence must not be ignored.

If roentgen study, such as the cholecystogram, is possible in conjunction with the drainage, four especially valuable details can be elicited in addition to what can be learned without it

- 1 Does the gallbladder fill well, and is it of normal shape?
- 2 Are there any calculi present?
- 3 Is the duodenal tube in the optimal position for drainage?
- 4 Does the emptying of the gallbladder as seen on the x-ray plates agree with the volumes and color sequence of the bile fractions obtained?

It is understandable that one may wish to perform a duodenal-biliary drainage when there are no radiographic facilities available. But it is not so justifiable, in my opinion, to make roentgen studies of the gall tract without a concomitant duodenal intubation, provided the latter is not specifically contraindicated by (1) acute infections of undetermined origin, (2) calculi liable to produce impaction, or (3) acute coronary or serious cardiovascular conditions.

CONCLUSIONS

Recent years have seen a shift away from biliary drainage as a therapeutic measure, it has come to be regarded only as a diagnostic medium. It is apparent, however, that there are toxic substances which may be removed only by periodic flushing of the biliary tract, and that the duodenal tube is an important adjuvant. In no other way are we as well able to follow the progress of our therapy. The benefit which patients with gall tract disease experience from periodic drainages cannot be fully ascribed to psychic reasons.

SYMPOSIUM ON CARDIOVASCULAR DISEASES

TREATMENT OF CORONARY THROMBOSIS*

N C GILBERT MD†

I would like to spend the time at my disposal in a consideration of the treatment of coronary occlusion in general, without taking up any one case history. The diagnosis we will assume to have been correctly made, and we will assume it to be understood that coronary occlusion is a very different condition than angina pectoris, even though the nature of the pain is identical in each. If the diagnosis of coronary occlusion is uncertain, as it may be occasionally, it is much better to err on the side of safety. It is better to make the mistake of treating a patient for coronary occlusion, even though an occlusion has not actually occurred, than of not treating him for coronary occlusion. It is a mistake that would be made only rarely, for the next few hours or a day or so will usually determine whether or not an infarct has occurred.

IMMEDIATE TREATMENT

We should not wait hours or days to begin treatment. Treatment should begin at once, as soon as the patient is seen. Occasionally treatment is not adequate because patients "do not appear sick enough," or for one reason or another. One cannot

* From the Medical Departments of Northwestern University Medical School and St. Luke's Hospital.

† Professor of Medicine, Northwestern University Medical Schools. Senior Attending Physician, St. Luke's Hospital.

always tell from the symptoms just which case is serious and which is not. It is much better to risk a bad psychological effect than an effect which, if it is not homicidal, may produce a cardiac cripple.

Unfortunately, an impression exists among so many students and physicians that not much can really be done in the case of coronary occlusion, that some patients get well and some do not and there is little for the physician to do except to advise bed rest and nursing care. There are several very essential things to be done at once that make recovery more probable, and the after-effects less serious and less crippling.

A patient with a coronary occlusion is often not only in pain and distress, but is frequently extremely apprehensive in regard to the outcome. Emotional as well as physical rest is necessary. The necessary emotional rest depends a great deal upon the attitude of the physician, who must obtain the patient's confidence from the first. An indifferent or an obviously alarmed or uncertain doctor does not inspire the degree of confidence which is necessary to offset the psychological shock which accompanies the accident. Nor is a patient's faith in his own future welfare increased by a doctor who is ostentatiously busy, or who wears what Sproul has referred to as a "funereal air of wisdom." The case should be handled easily, quietly, confidently and surely. And it should continue to be handled with just as little fuss and feathers as possible.

As is true everywhere in the practice of medicine and surgery, it is necessary to review just what has happened, what the conditions are, their consequences, and what means we may have at our disposal to meet these conditions.

There is of course one all-important fact and that is the presence of the occlusion and the resulting infarct. You cannot alter the occlusion itself. That is done and it cannot be undone. You can, however, do some things to make the results of the occlusion less serious. These should be done at once, as soon as the case is seen, and include the immediate administration of atropine and a coronary vasodilator drug, and morphine or another opiate if necessary for the pain. As soon as the patient is in bed oxygen should also be given.

For a certain proportion of the patients, the accident will be immediately fatal. If the patient survives the immediate onset, he should be moved after the emergency medication to where

he can be cared for most easily, comfortably and adequately. Usually this means the hospital. He should not be moved again until complete recovery has taken place. When once the patient is in bed in the hospital or in his home he should have constant special nursing care.

ATROPINE

When the occlusion occurs the body at once makes an effort to transport blood to the involved area by means of anastomosing vessels, extracardiac vessels in some cases, and very probably through other means of blood supply to the heart muscle, such as the luminal vessels and the thebesian veins.

At the same time, however, another event occurs which is very much to the disadvantage of the heart and its owner and offsets in part the efforts of the body to restore circulation to the involved area. This consists of a reflex vasoconstriction of the arteries in the uninvolved heart muscle. It increases the mortality rate and adds to the extent of the infarct and to the permanent damage done to the heart muscle in those who survive. In very large part it can be prevented and its prevention is important.

A few years ago, Manning, McEachern and Hall, and other workers in the Banting Laboratory in Toronto showed that when a coronary artery is occluded in the experimental animal there is at once a reflex vasoconstriction of the vessels in the uninfarcted myocardium, including the collateral arteries. This reflex vasoconstriction not only decreases the blood supply to the uninvolved heart muscle, but it hinders the efforts of the body to restore the circulation to the infarcted area. It adds to the probability of ventricular tachycardia and ventricular fibrillation and increases the extent of permanent damage and the probability of future incapacity. There are clinical reasons to assume that the same reflex vasoconstriction occurs in man. It is seen elsewhere in the body when an artery is occluded. If we keep in mind this vasoconstriction and its reflex nature, we are very sure that we can reduce the mortality.

The Toronto investigators observed that the death rate following ligation of the coronary artery in the dog was very low in the fully anesthetized dog. This has been confirmed in other laboratories. But if a ligature was placed loosely about the artery, and the dog allowed to recover completely from the anesthetic before the ligature was tied, the death rate was high. If

atropine was given at the same time that the ligature was tied or the vagi cut in the unanesthetized dog, the mortality was decreased to about that observed in the fully anesthetized dog. Bilateral removal of the stellate ganglion and the upper five thoracic ganglia also decreased the mortality to the same level as in the anesthetized dog. That it was some reflex mechanism responsible for the increased mortality in the unanesthetized dog was indicated by the effect of the atropine or vagectomy, and by the ganglionectomy. If they ligated one artery and measured the flow in an unobstructed artery, the flow in the unobstructed artery was found to decrease. That this was due to a reflex vasoconstriction and not to a fall in blood pressure was shown by the fact that it did not occur in the ganglionectomized dogs.

This work was repeated by LeRoy in our laboratory, with very similar results. By atropine alone he reduced his mortality from 70 to 50 per cent. This was not quite so great a reduction as Hall and his co-workers obtained, who reduced the mortality from 75 to 25 per cent, and to 10 per cent in the ganglionectomized dogs.

Since the work of Hall and his associates, we have used atropine routinely at once in all cases where the occlusion is at all recent. It is given in doses of $\frac{1}{100}$ or $\frac{1}{16}$ grain hypodermically. It has not been used intravenously because of unfavorable results observed a few years ago by C F G Brown following its intravenous use in experimental work. We have never seen significant increases in pulse rate or untoward results of any kind when atropine is given hypodermically. On the other hand, we have seen highly favorable clinical results as regards mortality and better progress during the recovery period in those cases in which it has been used in the first few hours.

I was much interested when talking to a physician in a small city to find that he had long ago made the clinical observation that patients with coronary occlusion to whom he gave atropine did very much better than others. For this reason he had used it routinely for years.

Relatively few patients enter a general hospital in the first few hours after a coronary occlusion. On our service, among thirty-five consecutive patients with definite history and findings and electrocardiographic changes who were seen in the first six hours, there were two deaths, or 6 per cent. One of these

at autopsy showed two old healed infarcts and was a cardiac cripple before the terminal infarct. The records of over half the patients we have seen on our service were lost when one of our number who was working on them was suddenly called to active duty in the Army. If we could include the lost records our percentage might be somewhat better but would be still statistically insignificant. Of course the next few cases might very materially alter the ratio one way or the other, but it is a much lower mortality rate than we had obtained previously.

Clinically, the atropine is given at once and repeated in four to six or eight hours, as indicated. Its use is discontinued as soon as conditions appear stabilized, which may be after the first dose or not until twenty-four to thirty-six or forty-eight hours have elapsed. We are usually able to discontinue its use after the first, second or third dose.

CORONARY VASODILATOR DRUGS

It would be supposed also that if a drug were used which would dilate the coronary vessels and increase the blood flow through the coronary arteries and their anastomosing vessels, there would be a better blood flow to the infarcted area, and the infarct would be smaller. There is ample experimental evidence to indicate that certain drugs do increase the coronary flow. Among these are drugs of the xanthine series, the nitrites, and papaverine. Smith and his co-workers showed that when aminophylline was given after the ligation of a coronary vessel in the dog, the infarct was smaller. Although some other investigators have not confirmed these findings, LeRoy took photographs in color of the infarcted area with and without the administration of a coronary vasodilator, and found the infarct smaller following the use of coronary vasodilators. Employing the same experimental procedure with dogs as in the atropine experiments, LeRoy reduced the mortality from 70 to 56 per cent by the use of aminophylline. Theobromine sodium acetate, although it is not suitable for parenteral use clinically, has a greater effect in increasing flow than does aminophylline. When it was used in the experimental animals, the mortality was reduced from 70 to 23 per cent.

It would appear from this work that drugs of the purine series are of definite value in the experimental animal, and we feel certain that this is also true clinically. A good indication of

this clinical value is the immediate cessation of pain in some cases following their administration alone. This result is understandable if they reduce the extent of the infarcted area, for the smaller the infarct the less the endocardial involvement and the less the probability of mural thrombi. We think also that they reduce the incidence of mural thrombi by reducing the extent of the infarcted area. The smaller the infarcted area, the less the endocardial involvement and the less the probability of mural thrombi.

Aminophylline may be used either intravenously or intramuscularly. For intravenous use the 10-cc or the 20-cc ampule, containing $3\frac{3}{4}$ or $7\frac{1}{2}$ grains, should be given, injecting the solution very slowly. Intravenous administration has the advantage of a more rapid action and the avoidance of the painful area which is apt to follow intramuscular use, but a disadvantage in that a fall in blood pressure may follow, especially if the solution is injected too rapidly. Other unpleasant symptoms may follow its too rapid injection, as palpitation, headache, nausea, or even precordial pain. On rare occasions a slight fall in blood pressure or palpitation may follow a slow injection, but such symptoms are never of sufficient importance to interfere with its use. When used intramuscularly, the effect of the drug is not so rapid, but it is more prolonged. A disadvantage is the pain, which may persist at the site of the injection for several hours. Much of this may be avoided by injection deep into the muscle. For intramuscular use, aminophylline comes in 2-cc ampules, carrying $3\frac{3}{4}$ grains or $7\frac{1}{2}$ grains.

There are other soluble salts of theophylline which are probably of equal value.

Papaverine hydrochloride is another coronary vasodilator of equal value with aminophylline. It has little or no hypnotic or analgesic effect and is not habit-forming. It can be given intravenously or hypodermically in doses of $\frac{1}{2}$ to $1\frac{1}{2}$ grains. For intravenous use, a dose of 1 grain should be sufficient. It also causes a fall in blood pressure, but I have never observed a significant fall to occur with either this drug or aminophylline. Morgan and Garr recently undertook a series of intravenous injections with each of the preparations, with especial reference to the effect on blood pressure. Aminophylline did not always cause a fall in pressure and occasionally caused a rise. The fall was always insignificant. Papaverine caused more of a fall than

did aminophylline, but never enough to be of consequence. The two drugs should never be used together, however, as under such circumstances a fall of serious consequence might result.

After the immediate emergency is over and the patient is able to take medicine by mouth, either of the preparations can be given orally. Papaverine should be used in doses of 1 to 1½ grains. Aminophylline or its equivalent theophylline preparation should be given in doses of 3 grains in enteric-coated tablets, or the insoluble calcium salicylate salts of theophylline can be used. The more insoluble any of these preparations are, the less likely they are to cause unpleasant symptoms, such as nausea or headache. The preparations insoluble in the stomach are absorbed readily from the intestine. There is no advantage in a readily soluble preparation for oral use. The acid stomach contents may precipitate out the alkaloid, and the absorption be the same as for the less soluble alkaloid. Or the stomach contents may buffer the acid of the stomach to the point where the alkaloid is not precipitated out, and the soluble salt absorbed by the stomach. If it is, there are more frequently unpleasant symptoms.

When drugs can be used orally, my own preference is for one of the *theobromine* preparations. The alkaloid theobromine has the advantage of carrying the full value of the active drug, and of being fairly insoluble in the stomach. It can be used in 5- or 7½-grain tablets or capsules. *Theobromine calcium salicylate* has the advantage of being relatively insoluble in the stomach and consequently is not likely to cause headache or nausea. It is absorbed readily from the intestines. It comes in 7½-grain tablets which should be given, one or two at a time, three or four times daily.

Theobromine calcium gluconate is another valuable salt, insoluble like the other calcium salts and, like them, less prone to cause nausea.

Of the soluble salts, *theobromine sodium salicylate* is the least valuable. It carries only 40 to 44 per cent theobromine and is the most apt to cause nausea. Unfortunately it is frequently used largely because of its easily remembered and readily written trade name of Diuretin.

Theobromine sodium acetate carries 60 to 66 per cent theobromine and probably the sodium acetate adds to its effect. It can be used in doses of 7½ to 10 grains, best in enteric-coated

tablets or in capsules The use of one of the drugs which increase the coronary flow should be continued all through the course of the treatment, three to four times daily, and for an indefinite later period

The nitrites are coronary vasodilators, but should not be used in coronary occlusion The marked fall in blood pressure which they produce may be sufficient to decrease the coronary flow in spite of coronary vasodilator effect There have been some fatal cases following nitroglycerin administration, and there might be more if the tablets of nitroglycerin used were more frequently of full strength Nitroglycerin tablets rapidly lose their full potency with age and exposure

Caffeme is a mild coronary vasodilator but has no value comparable to that of the other drugs

MORPHINE

Morphine, pantopon, or another narcotic should be given for pain, but it must always be given with at least $\frac{1}{100}$ grain of atropine Hall apparently believed at one time that morphine might accentuate the vagus reflex affecting the uninvolved arteries, but later he decided it made no difference in this regard LeRoy leaned to the opinion that the use of morphine by itself, without atropine, tended to increase the mortality in experimental animals Morphine is best not used after it has relieved the first onset of pain.

OXYGEN

We are none of us clever enough to determine from the degree of shock, or the symptoms, or by physical examination or laboratory findings just how much damage has been done in any one case A patient may have very mild symptoms indeed, and no shock at all, and yet die of a ruptured infarct For this reason I think that not only should atropine and a coronary vasodilator drug be used in every case, but that oxygen should also be given, however mild the case may appear Any possible harmful psychological effect from the use of oxygen can readily be obviated by a simple explanation that it is being used not because the patient is so ill, but to prevent him from becoming ill and to make him more comfortable Furthermore, the attitude of the patient toward its use is much different than it was a few years ago, provided the physician is not too apologetic

about it. Oxygen desaturation in some degree is always present in this condition. If we can add just a little to the oxygen carrying power of the blood—not only to the oxygen carried by the red blood cells but to the oxygen carried in loose solution in the plasma—we may decrease the amount of damage done. That oxygen is efficacious is evidenced by the frequency with which the pain, the sense of oppression and the anxiety cease at once upon its use.

Occasionally, for some reason which I cannot even speculate upon here, an alkalosis may develop when oxygen is used and proceed to the point of symptoms. It occurs rarely, but should be watched for. We usually check the carbon dioxide combining power of the blood after twenty-four hours.

Oxygen is best administered by means of an oxygen tent. The tent is more efficient and more comfortable than other means. The temperature can be adjusted to meet the patient's needs, and on a hot day in a room that is not air-conditioned this is an important consideration. If a tent is not available, use can be made of nasal catheters or of one of the various masks. Neither of the latter methods is as satisfactory or as comfortable as a tent. The use of oxygen should be continued for one or two days or longer, until the pulse and respiration are approximately normal and the cyanosis is improved.

TREATMENT OF COMPLICATIONS

In some instances *auricular fibrillation* or *auricular flutter* may occur at the onset. Either is best controlled by the regimen outlined and if it persists, as it does rarely, other treatment, which will be considered later, may be necessary. *Premature ventricular contractions* frequently occur, but do not of themselves require anything in the way of treatment. They may originate in an irritable focus present in the ventricular muscle before the coronary occlusion occurred, but usually they are an expression of increased irritability of the heart muscle due to insufficient blood supply and are best treated by continuing the aminophylline or papaverine and oxygen in adequate dosage.

Ventricular tachycardia is a constant succession of such premature ventricular contractions. It is a most serious complication and may eventuate in ventricular fibrillation and death. It is not likely to occur when atropine is used at once and aminophylline or papaverine and oxygen are employed.

Quinidine is frequently used in coronary thrombosis for the purpose of preventing ventricular tachycardia and the frequent ventricular fibrillation which follows. Quinidine has been shown to decrease the probability of ventricular tachycardia and fibrillation in the experimental animal when a coronary artery is ligated, which it does through its depressant effect upon muscle irritability, but it is to be remembered that it depresses the other functions of the cardiac muscle as well. It has been shown to cause the very condition for which it is used. We have seen untoward effects from its use, and do not employ it. It certainly should not be used routinely.

Heart block may occasionally occur, but this is not serious of itself unless too much attention is paid to it therapeutically. Again, aminophylline or papaverine is best for prevention and best for treatment if it does appear. Barium chloride should not be used. It reduces the coronary flow and causes an increased irritability of the heart muscle probably by reason of an increased ischemia. I see no reason for the use of magnesium sulfate intravenously or for giving potassium salts.

Shock is largely the result of circulatory insufficiency. It is absent or transitory when treatment is begun at once, except in the unusually severe cases with very extensive initial damage. Intravenous saline or glucose should not be used and I see no necessity for giving plasma or for transfusion. There are contraindications to the use of peripheral vasoconstrictor drugs. Blood pressure should be left where it is and not tinkered with. A return to previous higher levels is a good sign.

Edema of the lungs sometimes occurs when treatment of the occlusion is begun late, and may occur when treatment is begun at once. It is best cared for by one of the milder mercurial diuretics, used carefully. It is advisable to start with a small dose and avoid too free a diuresis. Hypertonic glucose will help the edema, but is best not used for the same reason that saline or glucose solutions are not employed intravenously in this disease. In a normal person under normal conditions, the use of such solution would make very little difference in blood volume, for as rapidly as fluid was taken into the blood stream, the excess would be eliminated by the kidneys. But where there is a decreased minute volume of blood being delivered by the heart, and a decreased volume flow through the kidneys in consequence, one would expect the blood volume to be increased.

Murphy has shown clinically that cardiac patients may be made worse by such solutions intravenously

I see no reason why *digitalis* should be used routinely and several reasons why it should not be employed at all early in coronary thrombosis. Occasionally in late cases it may be necessary. One does not wish to slow the pulse per se, and if one did wish to do so, *digitalis* would probably not do it. The pulse rate is usually best just where it is, if a normal mechanism is present, it will find its own optimum level. Atropine, a vasodilator drug, and oxygen will best care for the pulse and its rate by supplying more blood to the heart muscle. One certainly does not wish to increase the conduction rate. Contractility is best cared for by an increased blood supply to the heart muscle. Tonus is best left to the discretion of nature, for a longer muscle fiber may be a mechanical advantage. And irritability of the heart muscle, of all things, one does not wish to increase, for such an increase may result in ventricular tachycardia and ventricular fibrillation, which we are doing our best to avoid. We also feel that in full doses *digitalis* may cause coronary vasoconstriction. Laying aside all such considerations, there is no dearth of instances where patients have been made worse by its use.

Auricular fibrillation, when it occurs at the onset of the attack, usually ceases within a short time. If it persists, and if the heart rate is so rapid as to result in passive congestion, *digitalis* will have to be used to control the rate. In cases of passive congestion with a normal mechanism which occur later during the recovery process, *digitalis* can be used, preferably in small dosage. One must be ready to discontinue it if the output of urine does not increase or if the output becomes less. We prefer to get along without it if possible—and it almost always is possible—and to use mercurial diuretics for the edema. This is not because we do not like *digitalis*, but because we like it so much—in its proper place.

For *restlessness and sleeplessness*, recourse may be had to the milder barbiturates. We use phenobarbital almost routinely all through the period of bed rest and frequently beyond it. It is given in small doses, such as $\frac{1}{2}$ grain at night and $\frac{1}{4}$ grain in the morning. Such a dose decreases restlessness and is usually not enough to cause drowsiness. Larger doses can easily be used if necessary. If something additional is advisable for sleep, one

of the more rapidly acting and rapidly eliminated barbital derivatives can be used

Patients who have coronary accidents very frequently also have *spastic colons* and *spastic constipation*. The physician should make sure that the patient gets enough drinking water, especially the first thing in the morning, and he may prescribe one of the heavier mineral oils, or an emulsion of oil and agar. Such emulsions should not contain cathartic drugs. Solid white vaseline by mouth is not difficult to take, and does not have the unpleasant by-effects of the lighter oils. Mineral oils should always be taken before sleep at night and upon awakening in the morning, and never at or near meals. If cathartics are necessary, the mulder saline cathartics should be used and not the strong stimulating cathartics. Small doses of phenobarbital are very helpful in cases of spastic constipation. If necessary they can be combined with small doses of belladonna or one of the newer preparations which have an atropine-like action.

A similar regimen of diet and phenobarbital and belladonna, combined with the bed rest indicated in coronary occlusion, will be helpful if *duodenal ulcers* are present. Mucin may be used. Any more active treatment, such as alkali therapy, is practically never necessary. Gas and distention are not at all apt to prove of much consequence with the care of the diet and bowels already described. If necessary, enemas may be used for immediate relief.

Occasionally a patient may have a *hiatus hernia* which will usually respond to the same treatment as does the duodenal ulcer. A patient with hiatus hernia should be permitted to choose his own position in bed, and if he wishes to be in a semisitting position, or propped up, his wishes should be followed.

Diabetes should be treated adequately as diabetes, with insulin when insulin is necessary. But the insulin should be used in doses that permit a little sugar to show in the urine and permit the blood sugar to remain high enough to provide an adequate bulwark against a possible hypoglycemia, which would not only be uncomfortable but would be disadvantageous to the heart.

Pulmonary emboli call for the immediate use of atropine hypodermically and papaverine or aminophylline intravenously. As shown by de Takats and his co-workers, this decreases the mortality materially. *Peripheral emboli* may occur at any time from the first to the eighth week and possibly later, but we have

seen none in the cases that have been treated immediately. With peripheral emboli the question of embolectomy arises. Whether embolectomy is advisable will depend upon the patient's general condition, which is usually good since emboli usually occur late, and upon the nature and extent of the damage caused by the embolus. No chance should be taken on a possible amputation. In the case of *cerebral embolism* we are more helpless. Here again there is probably a halo of vasoconstriction about the embolus, causing a decrease in blood supply and adding to the damage. We have tried injection of the stellate ganglion in order to offset this vasoconstriction only once and the results were satisfactory in that one case. Oxygen might presumably help by enabling the blood to carry an additional supply to the area of the embolus. How much it helps we do not know, but we use it.

I see no especial point in the use of heparin or dicumarol in the ordinary case. If thrombosis occurs, neither drug should be expected to affect a clot already formed, and if the occlusion is due to another cause, as a subintimal hemorrhage, there is again no reason for assuming that either will help. On the other hand, in cases with a decreased coagulation time and in which the heparin curve, described by de Takats, is flattened, the possibility of an extension of the thrombus might be anticipated, and one of these drugs, preferably dicumarol, would be expected to be of value. The heparin curve is very easily obtained at the bedside.

A minor but uncomfortable complication at times is the occurrence of *stiff and painful joints*, involving especially the shoulder. This may be the consequence of prolonged bed rest from any cause. We have tried mild physiotherapy, such as light massage, passive motion, and heat, in two or three cases with favorable results, and we shall continue its use.

NURSING AND GENERAL CARE

There should be no hard or fixed rule about *bedside company*. It is best restricted, but care must be taken that too rigid restrictions do not make the patient more restless and apprehensive. There should always be a special nurse if possible, and the question of company and its length of stay can be left to her judgment.

All patients, both male and female, should use the bed pan, and not get out of bed. In exceptional instances men who make

hard work out of the use of a bed pan may be permitted a commode beside the bed

The *diet* should be barely sufficient for the daily caloric needs, easily digestible, and adjusted insofar as possible to the patient's wishes and tastes. It should maintain the blood sugar at high normal values, furnish sufficient protein, and not be such as to cause gas. Dietary management is more of a quantitative than a qualitative problem, the more food, the higher the metabolic rate and the greater the work for the heart.

Questions often arise regarding the use of *coffee*, *alcohol* and *tobacco*. I see no reason why coffee should not be allowed if it does not increase restlessness. The patient may be made more comfortable with it. The use of alcohol is a matter of individual judgment. It is of little therapeutic value but may be allowed in moderate quantities if the patient desires it. Tobacco is best omitted unless such omission causes actual restlessness, and even then its use should be very limited. Even in habitual smokers it may cause a decrease in coronary flow, especially when used on an empty stomach.

The duration of *bed rest* is a matter of judgment in each case, but it should never be less than eight weeks. The danger of emboli from mural thrombi is not over in four weeks, or six, or even eight, nor is the heart ready to resume its full duties so soon. Following bed rest, activity should be resumed gradually. Just how gradually will depend upon the response which is experienced when the patient is allowed up for short periods. Certainly an extra month should be allowed for convalescence after the period of bed rest, even in the most favorable cases.

COMMENT

I would suggest that the reader himself review the experimental work on coronary thrombosis from Hedblom to the present time, and the clinical results from Askanazy to the present time. This is better than accepting uncritically reviews which have been edited to the point where they are not altogether impartial.

Drugs such as aminophylline or papaverine, which frequently cause the pain of a coronary thrombosis to cease at once and favorably influence the course of the disease, and which quickly relieve pulmonary edema and paroxysmal dyspnea, must be of rather definite value. I would certainly wish one of them to be

used if I were the patient. When these drugs are used by mouth in angina pectoris, a great many people, including physicians, are able to carry on their usual duties in comfort who could not do it otherwise. There may be some doubt as to the exact manner in which the purine base diuretics and papaverine act to increase the coronary flow. They are not going to "cure" coronary thrombosis or angina pectoris, but they are valuable aids.

I think that the doubt expressed in certain quarters concerning the value of these drugs is a serious matter. Their use may mean the difference between life and death, between complete and only partial recovery, between invalidism from anginal pain and resumption of a normal life. This expressed doubt is especially unfortunate if it influences students who have not yet acquired sufficient critical background. It is not as serious as regards those clinicians who are taking personal care of their own patients and learn by clinical experience the value of these drugs.

ANGINA PECTORIS*

G K FENN, MD†

HISTORICAL BACKGROUND

EIGHT years before the Declaration of Independence was signed in Philadelphia, the Illinois country, which included Chicago, had recently been transferred from French to British control. Captain Thomas Sterling, on behalf of the British, took possession of Fort Chartres and the Illinois country in 1765. In 1768 the command passed to Colonel John Reed of the British Army. This historical reminiscence will serve to sketch in the local background of the year 1768, in which an English physician named William Heberden published a paper in the *Medical Transactions of the College of Physicians*. The title of this paper was "Pectoris Dolor" and in the course of it Heberden says, "But there is a disorder of the breast marked with strong and peculiar symptoms, considerable for the kind of danger belonging to it, and not extremely rare, which deserves to be mentioned more at length. The seat of it and the sense of strangling and anxiety with which it is attended, may make it not improperly be called angina pectoris." Thus was the label attached to the subject of our discussion this morning.

The pain of angina pectoris had been known before Heberden's time and had been previously described. Indeed, some of the best descriptions had been from the pen of lay persons. Seneca, whose life spanned the birth of Christ, and who wrote very bad tragedies in very good Latin, described his own anginal pain with great clarity. The Earl of Clarendon, in the seventeenth century, described the pain *in the left arm* suffered by his father, Lord Clarendon. He says, "he was seized on by so sharp a pain in the left arm for half a quarter of an hour, or near so much, that the torment made him as pale (whereas he

* From the Medical Departments of Northwestern University Medical School and St. Luke's Hospital.

† Associate Professor of Medicine, Northwestern University Medical School, Senior Attending Physician, St. Luke's Hospital

was otherwise of a very sanguine complexion) as if he were dead, and he used to say, 'that he had passed the pangs of death, and he should die in one of those fits' " He did

It was Heberden, however, who placed this disorder before the medical profession as a distinct clinical entity and who gave it the name it bears today

Now then, Heberden and his colleagues, among whom were Jenner, Hunter and Fothergill, thought that this disorder had something to do with the coronary circulation. It is popularly reported that Heberden did not mention the coronary circulation in his original report because he did not wish to worry his friend John Hunter, who suffered from anginal attacks. Hunter, however, seemed to be under no misapprehension about his trouble. He stated at one time that "my life is in the hands of any rascal who wishes to worry and tease me " He demonstrated the truth of this observation by dying suddenly at St. George's Hospital just after a rather acrimonious session with some of his colleagues. This rather ill-defined relationship to the coronary circulation was not made clearer by Heberden's paper in which he said, "On opening the body of one who died suddenly with this disease, a very skillful anatomist could discover no fault in the heart, in the valves, in the arteries or in the neighboring veins "

The ill-understood relationship between the coronary circulation and anginal pain caused all breast pain of this type to be called angina pectoris, and it was not until 1912 that our fellow-townsmen, James B. Herrick, taught us how to distinguish the pain caused by coronary occlusion and to make a diagnosis of coronary occlusion under the proper circumstances. In his article, Herrick removed a large number of patients from the general collection of those suffering from breast pain and placed them in a special group. Henceforth this group shall be known to suffer from coronary occlusion. In the present discussion the term angina pectoris will *not* be applied to those patients suffering from coronary occlusion.

THE ORIGIN OF ANGINAL PAIN

It seems obvious that anginal pain is related to the coronary circulation. It seems equally obvious that all anginal pain is not due to the same sort of coronary artery disorder. For instance, it is quite possible to have anginal pain with a relatively normal

coronary circulation In view of the fact that most anginal pain occurs after the age of forty-five years, it goes without saying that most anginal pain is associated with some *coronary artery change* However, in many cases the anginal pain must be predicated upon things other than the changes in the structure of the coronary arteries In the days when we saw very low red cell counts and low hemoglobin percentages in *pernicious anemia*, anginal pain was a common symptom of this disease Nowadays when the red cell count and the hemoglobin are usually maintained at normal or near normal levels, anginal pain is much less frequently observed It still occurs occasionally as a symptom of severe anemia Here, of course, the coronary vessels are not entirely at fault The impoverished blood is an important factor Likewise, one may encounter a *diabetic* in whom anginal pain occurs as the result of hypoglycemia The usual story is that the patient seems to be well controlled by insulin No sugar appears in the urine Upon questioning it develops that anginal pain is relieved by food The patient feels fine following meals. Further investigation reveals low fasting blood sugar levels Here again, it is not the structure of the coronary vessels that is primarily responsible for the pain It is the quality of the medium that is passing through them

Anginal pain may sometimes occur in association with marked *hypotension* One must remember that the coronary flow is a function of the mean blood pressure It is entirely conceivable that the blood pressure may at times be so low that a sufficient coronary flow is not available These represent a few examples of the occurrence of an inadequate coronary flow with a normal or relatively normal coronary vascular system

A rather unique situation lying somewhere between the foregoing and the frank coronary artery disorders is encountered in some cases of *hypertension* with left ventricular hypertrophy Anginal pain is usually a rather late manifestation in hypertension Its occurrence ordinarily signifies the appearance of structural changes in the coronary vessels This, however, is not always true In certain instances the muscle mass of the left ventricle increases rather rapidly to compensate for the additional load interposed by the hypertension The coronary circulation increases with the blood pressure up to a certain point and thus the increasing pressure carries its own compensatory increase in coronary flow At certain levels of cephalic pressure

the coronary flow becomes reflexly inhibited. We are then confronted with a situation in which an increased muscle mass cannot receive an adequate blood supply even though the coronary vessels are relatively normal. The coronary circulation cannot increase in the number of vessels. In addition, the coronary capillaries, which lie between the muscle fibers, have been stretched out by the muscle hypertrophy and dilation and this stretching tends to reduce the lumen of the capillary. Thus we have a normal, or relatively normal, coronary circulation which is unable for at least two reasons to meet the demand placed upon it by an increased cardiac muscle mass. And so it is that anginal pain may occur in such cases without the necessity of seriously damaged coronary vessels.

Mention of the cephalic inhibition of the coronary flow opens the question of *reflex inhibition* of the coronary flow in general. For a long time it was not admitted that the coronary vessels might undergo active constriction, or dilatation either as far as that is concerned. This is no place to enter upon a discussion of whether or not the coronary flow may be influenced by things other than blood pressure and cardiac work. That discussion has already filled many, many pages in the medical literature. Those of us, however, who have insisted that active coronary vasoconstriction and reflex vasoconstriction was a fact believe that a great weight of evidence is piling up to support us. Evidence has been brought forward to show that stimuli in at least three different places are capable of producing reflex coronary constriction. It is altogether likely that other sources for this reflex constriction exist.

A few years ago Hall in Toronto and LeRoy in our own laboratory showed the presence of reflex coronary artery constriction resulting from acute coronary occlusion. This work seemed quite conclusive and has modified our treatment of acute coronary occlusion. At about the same time, de Takats, Beck and I published some work that showed the occurrence of reflex coronary constriction associated with pulmonary embolism. Sometime later Gilbert, LeRoy and I demonstrated experimentally that the coronary flow may be greatly reduced by distention of the stomach. This work was carried over to the human where it was shown that anginal pain came on much more rapidly and easily when the stomach was distended and that this phenomenon might be prevented by breaking up certain re-

flexes All of this has been published at considerable length and need not be discussed now, but it convinces us that stimuli arising in various parts of the body are capable of producing reflex coronary constriction and that these reflexes added to an already impaired coronary flow may be responsible for anginal pain

In addition to those stimuli mentioned here there are doubtless many others that produce constriction of the coronary vessels in one way or another *Emotional stress* is notorious in this regard There is no doubt that the *smoking of tobacco* produces appreciable coronary constriction in some persons Altogether there are many things apart from structural change that may produce a reduction of the coronary flow in a susceptible individual

Now then, I distinctly do not want to leave you with the impression that I believe that most anginal pain occurs without structural change in the coronary circulation It is true that most persons suffering from anginal pain have a disorder of the coronary arteries The coronary artery disease itself many times produces the anginal pain but the other factors that I have mentioned often enter into the picture The anginal pain caused by obstructive changes in the coronaries has certain distinctive characteristics that I shall discuss in a moment At this point I wish to call your attention to certain cardiovascular disorders that produce a pain that is often confused with the pain of angina pectoris

Aortitis produces substernal pain that is very similar to that produced by coronary artery disorders It is a burning pain that may have the same location and radiation as the pain that we have been discussing Yet for purposes of this discussion, at least, aortic pain must not be confused with true anginal pain It was not so long ago that most anginal pain was attributed to aortic causes, and Sir Thomas Clifford Allbutt rather scornfully called the adherents of the coronary artery theory the "coronarians" In this category comes also the pain of aortic insufficiency

The *rupture of a dissecting aneurysm* may cause pain that is very difficult, if not impossible, to differentiate from pain of coronary origin This event is more likely to be confused with a coronary occlusion than an attack of angina pectoris but the pain element is the same *Pericarditis* may for a time be confused with anginal pain

There are, of course, a host of pains of noncardiac origin that

may be confused with anginal pain but there is no time to discuss that phase of the subject here. It is well to remember, however, that all chest pain does not have its origin in the coronary circulation.

CLINICAL PICTURE

Angina Pectoris

Now that we have dealt with the origin of anginal pain it might be well to discuss the pain itself. It would seem almost unnecessary to describe the pain of angina pectoris when it has been done so many times but we must try to differentiate the several varieties of anginal pain as well as we can in order to have a logical approach to the management of each case. For the purpose of this discussion let us say that the term *angina pectoris* is applied only to a certain variety of anginal pain. That variety is the sudden attack of breast pain that comes on without much warning and is very severe indeed. The patient is seized with an attack of pain that is located beneath the sternum usually at the junction of the lower and middle third. The pain comes on suddenly and reaches its full development almost immediately. The patient has no time to do anything but stop where he is and seize upon the nearest object for support. The pain may be and usually is referred to the left shoulder and down the left arm. It goes down the inner aspect of the arm and may extend into the middle and ring fingers or it may terminate abruptly at the inner aspect of the elbow. Rather frequently the pain is referred to both shoulders and arms, and sometimes it may go to the right side only. It is not infrequently referred upward to the neck and the jaws and it may cause a sensation resembling toothache. Much less frequently it is referred into the back at the base of the neck. Very rarely it may be felt between the scapulae. It may also be referred downward but with much less frequency. When the pain is referred downward toward the abdomen it is sometimes difficult to differentiate the entire episode from an attack of upper abdominal pain. It seems to me that this variety of angina is particularly important because it is so likely to be overlooked and attributed to an abdominal disorder.

Together with the pain there is a *sense of constriction* in the chest. This has been described as a viselike pressure or a sense of fullness that resembled a pressure from within. There is also

a certain *feeling of apprehension* that does not accompany other varieties of pain. This sense of apprehension has received a number of titles among which "the icy hand of death clutching the heart" and "a sense of impending dissolution" are perhaps the most descriptive

The pain with its attendant phenomena comes on as described, lasts a varying period of time usually not exceeding fifteen minutes and then subsides as quickly as it came. During the attack the patient remains perfectly quiet. He seldom makes a sound. His breathing is slow and shallow. Dyspnea is no part of this attack. It seems that the patient voluntarily inhibits his movements from fear of greater pain as a result of movement, even breathing. During the attack the patient's face is gray, a mixture of pallor and cyanosis. His lips appear blue and he looks very ill indeed, as he is. With the subsidence of the attack the patient takes a long breath, slumps back relaxed in his chair, perhaps smiles and apologizes and except for a great exhaustion he seems to feel quite well.

This is a typical attack of angina pectoris. It is a burning, chest-filling pain, with a sensation that the ribs are being pressed into the chest and a sensation that every breath may be the last. With the subsidence of the attack, no signs are left behind. There is no change in the blood pressure or pulse, no physical signs that would indicate that a serious crisis had just been passed. It is important to remember this, since often the aftermath produces the only evidence to differentiate such an anginal attack from an occlusion of a coronary artery. It is my opinion that the attack just described is always precipitated by an active constriction of the coronary circulation. This is not to say that such attacks frequently occur in the absence of coronary artery disease. Not at all. A pathologic change in the coronary artery is usually present but still the determining factor in the attack is that of active constriction of the coronary vessels.

Angina of Effort

When marked coronary artery disease is present, one is likely to see a different type of anginal pain. This is the pain that begins almost exclusively with exercise and builds up rather slowly. The patient notes the pain as he walks along the street and he knows if he goes too far it will become quite severe. BUT, he is able to go along until the pain slowly reaches a cer-

tain point in severity and then he may stop and rest for a time and the pain slowly subsides. Thus by exercising and resting alternately, he may carry on fairly well. In other words, he has the pain more or less under control and he is able to escape severe attacks by watching his behavior. This type of pain is the result of an insufficient coronary circulation, either functional or organic, and is quite different from the attack of angina pectoris that was previously described.

Atypical Anginal Pains

We must also consider the somewhat atypical pains that point toward a coronary origin. Lord Clarendon spoke of his father's pain which was confined to the left arm only. As a matter of fact, the pain may be confined to any of the areas of reference and may be of any degree of severity. We must therefore carefully investigate all of the pains in this locality that occur in individuals of a certain age group and determine whether or not these pains may be of coronary origin. Pain any place in the chest or arms that has this peculiar squeezing character and that is predicated upon exercise must be investigated for a coronary origin.

Illustrative Cases

It is difficult to present before the clinic an example of angina pectoris, for it is seldom that the patient times his attack to coincide with the hour of the clinic. Only once in many years of teaching has the attack occurred at the proper time. I have one or two records that I exhibit rather frequently to demonstrate some of the things that we have talked about.

A. P., a gentleman aged sixty-six years, first came to me because of pain in the left shoulder and arm. He operated a small machine shop where he specialized in the repair of automobile carburetors and generators. His office was situated on a balcony above the work floor and he noted that when he went up and down the stairs to his office too frequently he developed a pain in the left shoulder and arm. He had assumed that this pain was due to a local disturbance in the shoulder and he had discovered that if he immersed his arm in hot water the pain usually subsided. He confessed, however, that if he merely sat down and waited the pain disappeared in a few minutes anyway. He also had attacks of the same sort when he was driving his car in heavy traffic and became irri-

tated by his inability to move along rapidly. When the attack came on under these circumstances he stopped his car at the earliest opportunity and waited for the pain to pass.

I was very curious about the relief he obtained from immersion of the arm in hot water but he insisted that there could be no mistake about it and that he kept a pan of water heated in his shop exclusively for this purpose. I was quite convinced from the history and from the location of the pain that I was dealing with an anginal affair. I could not see, however, how the local application of heat could be effective in stopping the pain. It occurred to me, however, that this immersion of the arm in hot water might provoke a general vasodilatation and thus relieve the anginal pain. I suggested that next time he immerse his right arm in the water and observe the effect on the pain in the left arm. He saw no point in this procedure but he agreed to undertake it just to humor me. To his great surprise it worked just as well as the immersion of the left arm. This then was a case of moderately severe anginal seizure that was relieved by rest and by heat. Later under appropriate management these attacks were reduced materially in number and severity.

About a year after this gentleman came under my observation he had an unusually severe attack of pain one afternoon at the shop. Immersion of the arm in water, nitroglycerin under the tongue and other measures failed to have any effect on the pain. Instead of subsiding in ten or fifteen minutes it lasted for three hours in such a severe form that he was unable to get home. When he did arrive at home some three or four hours after the onset of the pain he became nauseated and vomited. His pain still continued but was less severe. He stated that the pain was almost identical with that from which he had suffered for the past months. It extended slightly more into the chest and was more violent than most of his previous attacks. I sent him to the hospital, of course, as soon as my attention was called, and subsequent examinations proved that he had suffered a coronary occlusion.

Here then was a man who had suffered numerous attacks of anginal pain without anything more than temporary disability. The same sort of pain with certain modifications and sequelae proved to be the principal symptom of a coronary occlusion.

R. H., a man of fifty-eight and an executive in a highly competitive insurance business, began having attacks of substernal distress that were brought on by rather moderate exercise. He noted that he could no longer walk from the station to his office, a thing

that he had done for years without trouble. He has never had a crushing anginal attack but very uncomfortable anginal pain followed upon every attempt to get actively about. After this had been going on for about a year he took a six-months' holiday and went abroad to visit his daughter. Very soon he found himself doing things that he would not dream of attempting at home. Soon his anginal pain had virtually disappeared and it took a great deal of exercise to cause him to feel it at all. Naturally, he was delighted, only to be greatly disappointed when his symptoms promptly reappeared when he returned home and resumed his work. This seems to me to demonstrate the effect of emotional stress in promoting painful episode of this sort.

I could go on indefinitely presenting case records to show the variable nature of this disorder and the different forms under which it appears, but perhaps we should now approach the discussion of what to do about it.

MANAGEMENT

Nothing in the field of medicine requires a more careful individual study than does the case of angina pectoris. First, we must be sure of the diagnosis. Almost everyone nowadays realizes the seriousness of a diagnosis of angina pectoris and we must be careful not to subject our patient to the mental burden of this diagnosis unless we are sure of our ground. Secondly, the general management and the specific treatment are greatly influenced by the correctness of the diagnosis.

General Measures

When the diagnosis seems to be definitely established it becomes the duty of the physician to determine, if possible, what sort of anginal pain he is dealing with. Is it effort alone that produces the distress or is it the pressure of business or emotional stress? Or is it a combination of several contributing factors? It is necessary of course, to greatly *modify the habits* of the patient in many instances and a study of the immediate causes of his anginal pain is the most important guide to the modification. Unless the patient is engaged in an occupation that requires hard manual labor, it is surprising how frequently he can carry on his usual occupation with certain modifications. Perhaps it will be necessary to shorten his working hours, frequently short vacations not too far apart will work very well.

Avoidance of controversial subjects and avoidance of any activity or occupation that causes emotional stress must be insisted upon. In other words, the patient may play golf if he does not take his game too seriously. The same applies to bridge or to attending football or baseball games or even to listening to the radio under certain circumstances. A careful study of the entire situation will often show how the attacks may be greatly reduced. A patient may be able to do a certain amount of exercise in the summer that is impossible in the winter. It is well known that many attacks are precipitated by breathing cold air. The same is true of exercise before and after meals.

This brings me to a discussion of the relationship of the *gastro-intestinal tract* to the occurrence of anginal pain. It is well known that anginal attacks occur more frequently following meals and in the presence of gastro-intestinal disorders. It has now been shown that distention of the stomach and bowel, either by food or by gas, causes a sharp reduction in the coronary flow and causes anginal pain to come on with less provocation. Therefore, as a general proposition, the gastro-intestinal tract should be kept in good order. Any tendency toward constipation should be overcome. A study of the patient's peculiarities will show what foods he does not tolerate well. The known gas-formers should be avoided. And above all the patient should avoid any provocative activity after meals. Indeed, he should avoid large meals.

Mental tranquillity is of great importance in dealing with anginal pain. We are all familiar with the greater prevalence of anginal attacks during periods of financial crisis or during an election year or even in wartime. Of course it is not always possible to achieve mental tranquillity. We cannot, apparently, avoid having financial depressions occasionally and we do not want to avoid election years. We can attempt to keep our patients out of many emotional crises and we can teach the patient to avoid too much mental excitement. It is surprising how much a bit of self-control will accomplish. When the patient is taught that he *cannot afford* to get angry or that he *cannot afford* to argue about trivial subjects, his life becomes very much more tranquil. The patient must realize that violent argument accomplishes very little anyway except to precipitate anginal attacks in susceptible individuals.

Treatment of the Attack

After we have studied the patient carefully to determine what general management to apply to his case we come to the matter of administering drugs. For the treatment of the attack, *nitroglycerin* under the tongue has no serious competitor. We still find most sufferers of this disorder carrying the small vial of hypodermic tablets of nitroglycerin, grain $\frac{1}{100}$, in his pocket. One of these placed beneath the tongue will ward off most attacks or at least shorten the duration. This dosage may be repeated frequently without apparent danger, but to assume that unlimited amounts of nitroglycerin are quite innocuous is a mistake. It does lower the blood pressure to a considerable degree and when this effect is pushed unduly, ill effects may result. Inhalation of amyl nitrite from the well known amyl nitrite pearl is almost as effective as nitroglycerin but it is perhaps slightly more dangerous. These remedies are so well known that I need not talk further about them here.

As a general rule, *narcotics* are in the class of bad treatment for attacks of angina. The attacks occur too frequently and in any event if the pain persists long enough for the physician to arrive and prepare and give a narcotic one should doubt the diagnosis.

Drug Prophylaxis

The next task is to attempt to forestall the attacks. As already pointed out, prevention is first a matter of management rather than drug treatment, but unfortunately it is impossible to "manage" away most attacks of angina. We therefore prescribe one of the drugs that has the effect of dilating the coronary vessels. The most trustworthy of these are the *theobromine* and *theophylline compounds*. In our own clinic we use specifically alkaloidal theobromine, 5 grains four times a day, theocalcin, which is theobromine calcium salicylate, $7\frac{1}{2}$ grains four times a day, aminophylline, which is theophylline with ethylenediamine, 3 grains three or four times daily. The latter may be given parenterally but this is rarely if ever necessary in the treatment of angina pectoris. Under certain conditions in which it is impossible to have medication retained in the stomach the intramuscular administration of aminophylline is indicated. Parenteral administration is usually limited to the treatment of coronary occlusion.

I feel that I should offer a few words about the theobromine and theophylline compounds, because there seems to be doubt in certain quarters concerning their efficacy. This is a question that the physician must answer from his own experience. Those of us who have done experimental work with these drugs cannot fail to be impressed by the effect on the coronary flow in the animal, and their efficacy in clinical usage seems equally plain to me. A high percentage of my own patients are greatly benefited by the proper administration of these drugs. It is true that one must again study the individual case. A routine handling is not satisfactory. Some patients will not tolerate one form of medication that may be given with impunity to another patient. I cannot see how careful administration of adequate doses of these purine base preparations will fail to benefit a large number of patients. It is, of course, obvious that in those patients whose vessels are rigid and sclerotic, dilatation by any means is almost impossible.

A striking testimonial to the efficacy of theobromine and theophylline is obtained when one attempts to persuade patients, particularly physicians, to get along without either drug after they have been rendered reasonably comfortable by its use. One obstacle to their use formerly lay in the gastric distress that accompanied their administration. This has been largely obviated by the newer preparations, and if the medication be given together with the meal, difficulty is seldom encountered.

Other drugs that are used for the dilatation of the coronaries are the *nitrites*, apart, of course, from those nitrites already mentioned. In my hands the effect has been too transient to be dependable. Furthermore, I believe the purine bases to be superior in effect.

The administration of a small dose of a *barbiturate* often seems to be effective in reducing the number or severity of anginal attacks, but I do not favor the combination of barbiturate and purine base in a single tablet. I prefer to be able to vary the dose of one or the other drug at will.

The parenteral administration of certain *tissue extracts* has been effective in some patients. This material is surely worth a trial if difficulty is encountered in controlling attacks by other means. In some cases, indeed, it seems to be superior to any other medication. Unfortunately its administration is time-consuming and this fact has had something to do with its less widespread

popularity When this material is used it must be given in adequate doses. This means a daily injection for a time, with a longer time interval later as indicated The patient may be taught to give his own injection but this always seems to me to be throwing too much responsibility upon the patient

The administration of *male sex hormone* (androgen) has been recommended Androgen has not been particularly efficacious in the relatively few cases in which I have used it Perhaps I have not been sufficiently persistent because in a few of my cases the results have been rather striking

Drugs That Should Not Be Used—There are a few contraindications in the use of drugs that probably should be mentioned Any drug that increases cardiac work should be avoided or given with great care The most common of these are *thyroid*, *epinephrine*, *ephedrine* and *benzedrine* As you may know, *digitalis* is one of my pet abominations I am already on record with my belief that digitalis may sometimes produce anginal pain To my mind the only indication for digitalis, apart from auricular fibrillation, is congestive heart failure, and congestive heart failure and angina pectoris seldom coexist I cannot see how digitalis can be of any benefit in angina pectoris and I feel sure that it may at times be harmful

Surgical Measures

Some years ago *cervical sympathectomy* or *injection of the nerve trunks* was practiced as a means of interfering with the pain. Either may be justified in certain instances but is not recommended for widespread adoption Likewise, *thyroidectomy* has been effective in controlling anginal attacks but the cases must be selected with great care and this surgical procedure is not to be considered as a general routine treatment of angina pectoris

The surgical operations pioneered by Beck and O'Shaughnessy have been interrupted for the present. Perhaps this work will be resumed later and result in a means of creating an auxiliary coronary flow

PROGNOSIS

I know of no situation in which it is more difficult to make an accurate prognosis The patient may die in his next attack and he may live for years Because of this uncertainty it is well that some member of his family be told of the possibilities. As a

general rule, it is unwise to tell the patient all of the possibilities, since few of us are able to face immediate extinction with mental tranquillity.

To those of you who may suffer from this disease, let me say that you travel in distinguished company. Some of the most famous men of history have suffered from the disease and even died from it

HYPERTENSION

CHAUNCEY C MAHER, M.D.*

DEVELOPMENT OF OUR KNOWLEDGE OF HYPERTENSION

By definition hypertension, or hypertensive vascular disease, is a syndrome in which there is persistent elevation of the blood pressure and left ventricular enlargement. Nephritis may or may not be a factor and it is generally accepted that complications are varied and frequent.

The term hypertension is a modern concept, as recent as the blood pressure instrument, which was introduced into the United States in 1902 by Harvey Cushing. The disease entity is of course much older, possibly as old as man. As a medical concept it probably began with recognition of cardiac enlargement. Lancisi was one of the first to recognize increase in heart size as an abnormality in his search for the causes of sudden death in Rome in 1709. He later wrote a book "Cardiac Aneurism" which was the terminology of cardiac hypertrophy of that day. There is little doubt that some of his cases are the same disease as those we now classify as hypertensive vascular disease complicated with acute coronary thrombosis.

About a century later, Richard Bright brought the subject of albuminuria before the profession, showing a relationship between chronic renal disease, cardiac hypertrophy, and apoplexy. The emphasis of the era was concerned with the renal aspect of the problem and therapy was directed toward kidney disease. Later it was determined that albuminuria was not always manifest early in the course of the disease, and sometimes was a very minor factor. Information accrued on arterial disease, and arteriosclerosis became part of the clinical concept.

With the advent of the blood pressure instrument in the present century, our modern view has emphasized the hyper-

* Associate Professor of Medicine, Northwestern University Medical School. Attending Physician and Chairman of the Department of Medicine, Cook County Hospital.

tensive state, with treatment directed toward blood pressure reduction

These three phases of the development of knowledge of this disease do not include a tremendous amount of research on many finer points which have amplified and extended the profession's information. Refinements of urinalyses, renal function tests and blood chemistry determinations have contributed to the study of the role of the kidneys in the problem. The x-ray and the science of fluoroscopy have augmented the knowledge of the changes in the shape and size of the heart and aorta. The electrocardiographic method has been an aid in the study of the complication of coronary thrombosis, and also in the study of left ventricular hypertrophy in the shift of the electrical axis. Ophthalmoscopic examination of the retinal arteries has given direct pictures of the vascular status.

PATHOGENESIS

With widespread use of the blood pressure instrument, it has been recognized that hypertension is associated with a number of disease entities. Chronic lead poisoning, formerly more common than now, is often linked with increased blood pressure and vascular disease. Other diseases recorded are less common, such as Paget's disease of the bone, coarctation of the aorta and congenital cystic kidneys. Chromaffin tumors of the adrenals have been proved by surgical removal to be the cause of paroxysmal hypertension. Others include periarteritis nodosa, brain lesions with increased intracranial pressure, polycythemia vera, arteriovenous aneurysm, hypothyroidism, and heart block.

Malignant nephrosclerosis has been separated as a distinct clinical entity, with exceptionally high blood pressures, a short progressive fatal course, and widespread arterial involvement particularly evident in the kidneys.

The role of syphilis in hypertension has also been of considerable interest. In the United States it has been conceded generally that the two diseases are unrelated, while in France, syphilitic hypertension has been recognized as a specific entity.

Experimentally, in the animal laboratory there have been repeated efforts to produce an artificial hypertension by surgical removal of kidney tissue, injury to the kidneys by chemicals or x-rays, or by production of multiple renal emboli. While some of these methods were somewhat successful they received com-

paratively little attention until Goldblatt achieved a method of partial clamping of the renal arteries and a satisfactory and practical procedure for consistent production of a hypertensive animal. The repetition of these operative procedures by decreasing the renal arterial blood supply has re-emphasized the renal aspect of the problem, with particular regard to the blood supply.

Within the last decade, the hypertensive vascular syndrome has been linked with chronic pyelitis and pyelonephritis. Our own studies along this line have suggested that the relationship included many urologic entities, indicating that the factor of obstruction in the urinary tract was a potent etiologic agent, as well as infection. We have noted frequently the association of hypertension with prostatism, renal stones, hydronephrosis, bladder diverticula, and have shown statistically that hypertension was more common in the urologic type of patient than in a control group of similar ages without urinary tract disease.

EFFORTS AT CLASSIFICATION

For many years it has been common practice to classify hypertension into two groups—the nephritic, representing about 5 per cent of the total, and the non-nephritic, the remaining 95 per cent. This latter group was labeled as *essential hypertension*, implying the absence of a causative factor, particularly a renal background. Actually, however, in clinical practice the label of essential hypertension was too often given without diligent investigation of all the clinical aspects of the individual case. Many of the aforementioned disease entities were not excluded. More recently, there has been an obvious trend toward classification of hypertension into a greater number of groups, and a gradual insistence that all cases demand more detailed study than in the past, abrogating the term essential hypertension. Most practitioners have been impressed that hypertensive patients have certain subjective symptoms and objective findings in common, and also with the fact that paradoxically there are divergencies that appear to separate individual cases. Complications often mar the true pattern of any individual patient.

Illustrative Cases

It is only possible to offer a few examples in this paper, illustrative of the similarity as well as the variability of the clinical pictures of hypertensive vascular disease. The following records

are offered in a chronologic sequence of medical events, as it has been our experience that the clinical pictures are best portrayed by this method of presentation

Case I

(Observed from 1937 to 1942)

1882—Mr M E V, a lawyer, married, was born in a rural community His father died of apoplexy at the age of 74, and his mother of bowel obstruction at 62 A sister died of tuberculosis, and another of pneumonia

1896—Age 14, he had "bilious fever"

1900—Age 18, mumps was followed by atrophy of one testicle

1904—Age 22, measles

1914—Age 32, he was married

1928—Age 46, renal colic and hematuria occurred His blood pressure was said to be normal at this time

1930—Age 48, herpes zoster and mild arthritis were noted General examination in a university clinic recorded blood pressure as normal

1937—Age 55, re-examination in a university clinic revealed slight albuminuria and slight elevation of blood pressure Cardiac irregularity was noted (ventricular extrasystoles)

Routine examination later this year showed a negative record of subjective symptoms except for apprehension regarding the blood pressure elevation and the albuminuria The blood pressure level was 180/120 and a systolic murmur was noted at the heart apex The electrocardiogram showed a left axis deviation, the roentgenogram, an enlarged left ventricle, prominent aortic knob, and a substernal thyroid enlargement. The basal metabolic rate was normal, renal function tests were normal, blood counts normal, and the Wassermann reaction was negative.

1938—Age 56, an uneventful year with no subjective symptoms and no significant changes in the objective findings Blood pressure was 190/114

1939—Age 57, course continued without significant change Examination by a urologist showed "mild prostatic hypertrophy and slight residual bladder urine" Pyelograms were considered normal

1940—Age 58, no significant alteration of course noted Blood pressure 180/110

1941—Age 59, the course was uneventful during the early part of the year A routine examination, however, disclosed the presence of a systolic-diastolic murmur at the base of the

heart and change in blood pressure to 150/80. The cardiac roentgenogram showed no change in size and the electrocardiogram was unaltered.

In October, while on a vacation, in a mountain resort, the patient suffered a transient attack of nocturnal dyspnea with no pain. He subsequently noted dyspnea with exertion, and fatigue. On returning home a few weeks later, he was found to present evidence of cardiac insufficiency and was hospitalized. The electrocardiogram showed significant changes with coronary type of T waves in Leads I and IV. Compensation was readily regained with bed rest and fluid balance maintained after leaving the hospital.

1942—Age 60, this year was one of steady decline. The patient was unable to accept complete invalidism and alternated between a state of mild cardiac failure with activity and compensation when he was at bed rest.

In September, the final period of hospitalization was effected, and death occurred in November. During this last episode, the patient showed increased fluid retention in the lung bases, the liver, and lastly in the lower extremities. The blood pressure ranged around 150/70 with the persistence of the systolic diastolic basal murmur. In the latter part of the course the blood pressure fell to the lower levels of 100/60. Evidence of renal failure developed with increased amounts of albumin in the urine, a decrease of total blood protein, increased nitrogen levels in the blood, dyspepsia, anemia and mental confusion. The final episode of the course was concerned with severe chest pain, repeated hemoptysis, cyanosis, and air hunger, with increased edema throughout the body and finally death. The clinical picture was that of marked cardiac insufficiency, renal failure, mental confusion and malnutrition.

Autopsy Record

The heart weighed 670 gm, with an incompetent aortic valve measuring 10 cm. The mitral valve showed fibrous thickening. There was one large old infarct in the left ventricle with a mural thrombosis and multiple small old infarcts.

The pleural cavities both contained fluid (700 cc. left and 150 cc. right). Both lungs showed pulmonary thrombi and infarcts. There was marked pulmonary arteriosclerosis. There was chronic passive congestion of the parenchymatous viscera, and recent thrombosis of both axillary and lateral thoracic veins.

The kidneys were labeled "arteriosclerotic and contracted" with a cortical cyst in the left kidney. The middle lobe of the prostate was markedly enlarged with mild enlargement of the lateral lobes. The bladder musculature was hypertrophied with marked trabecu-

lation of the wall There was a substernal cystademonia of the thyroid, hypertrophic arthritis of the spine, and generalized arterio sclerosis

Case II

(Observed 1936 to 1943)

- 1899—Miss M F, single, clerk, was born in Chicago Her father died of pneumonia at age 67, and her mother of heart trouble at 73 One sister died of tuberculosis at 22 Four sisters and one brother living, have no knowledge of hypertension
- 1910—Age 11, she had "scarlatina" with no known complications
- 1911—Age 12, onset of menstruation "Swollen neck glands" were noted this same year
- 1917—Age 18, tonsils and adenoids removed
- 1922—Age 23, appendectomy.
- 1932—Age 33, gastro-intestinal study was made with diagnosis of spastic colon This same year she had a laparotomy and one ovary was removed Digestive symptoms were increased
- 1933—Age 34, in December, the patient was held up and robbed, and had a "mild nervous breakdown" She was told her blood pressure was elevated
- 1934—Age 35, she was hospitalized for "nervous exhaustion" Blood pressure again recorded as elevated.
- 1935—Age 36, hospitalization was accomplished for treatment of "spastic colon" Also, she was told she had migraine headaches
- 1936—Age 37, subjective complaints were nervousness, fatigue palpitation, dyspnea, frequency of urination, distention of abdomen, nausea and constipation Objectively, the patient was mildly obese with a blood pressure of 260/160, whe first recorded There was a systolic murmur at the apex and base of the heart and no evidence of cardiac insufficiency The Wassermann test was negative, blood counts normal urine negative, renal function tests normal, blood nitrogen elements not elevated The electrocardiogram was essentially negative except for a mild left axis deviation The cardiac roentgenogram showed only mild left ventricular hypertrophy Intravenous urograms were negative
- 1937—Age 38, the patient volunteered for splanchnicectomy and was hospitalized for extensive study The blood pressure showed a moderate decrease during sleep and with barbiturates Roentgenograms of the gallbladder, stomach and bowel were negative Gynecologic and urologic examinations were reported negative Ophthalmoscopic examination showed only

mild changes Renal function tests and blood chemistry findings were all normal The operative procedure was performed in two stages without incident except for acute pleuritis during the convalescence The preoperative blood pressure ranged around 250/140 Immediate postoperative level was 120/100, and on leaving the hospital 200/120

- 1938—Age 39, the patient was hospitalized for study Her subjective complaints were essentially unchanged and the objective findings were unaltered The blood pressure was 218/134 The urinalysis, blood counts, blood chemistry were within normal limits The electrocardiogram and cardiac roentgenogram showed no significant alterations Thiocyanate therapy did not change her subjective symptoms or lower the blood pressure levels
- 1939—Age 40, course unchanged She was hospitalized for a short period of time and the blood pressure was recorded as high as 270/170
- 1940—Age 41, the subjective and objective findings remained approximately the same, blood pressure record was 260/164 During the latter part of the year, she began to complain of cardiac pain with reference to the left arm The electrocardiogram showed increased width of the QRS complexes up to 0.12 second, with more marked inversion of the QRS in Lead III
- 1941—Age 42, the course was marked by frequent attacks of cardiac pain referred to the left arm and dyspnea became a more prominent symptom She collapsed while at work and was suspected of having an acute coronary thrombosis. Electrocardiogram showed progression of the width of the QRS complexes and the typical pattern of left bundle branch block There was no evidence of renal failure and cardiac compensation was maintained Blood pressure was recorded at 260/160
- 1942—Age 43, there was marked exaggeration of all symptoms and development of cardiac insufficiency Cardiac pain and dyspnea were even more frequent. The patient developed a tachycardia, gallop rhythm, enlarged liver and dependent edema The blood pressure was 220/140
- 1943—Age 44 further adverse progression of symptoms and findings was noted The patient became decompensated and bedridden, with leg edema and fluid in the lung bases With hospitalization, sedation, complete bed rest, and diuretic management she showed some recession of symptoms with a weight loss of 20 pounds of edema fluid Her course up to

the present date has remained approximately the same with moderate cardiac failure with edema. The blood pressure level has remained consistently high, around 240/130. She is still living

Case III

(Observed from 1933 to 1937)

- 1871—Mr O J M, executive, married, was born in Chicago His father died of appendicitis at 37, his mother of heart disease at 76, and two brothers and one sister of heart disease Two sisters are living
- 1881—Age 10, he had the usual contagions of childhood prior to this age with no complications
- 1889—Age 18, a pulmonary hemorrhage occurred, diagnosed as pulmonary tuberculosis
- 1906—Age 35, he was married There were no children
- 1916—Age 45, minor attacks of "bronchitis" and rather frequent colds" occurred
- 1926—Age 55, he attributed frequent "bronchial colds" and chronic cough to tobacco smoking
- 1933—Age 62, the patient developed an acute lobar pneumonia and was hospitalized for oxygen therapy Shortly after entrance to the hospital an auricular fibrillation developed which terminated spontaneously within 24 hours During the convalescent period he developed an interlobar pleural effusion which was aspirated showing clear fluid The remainder of his convalescence was normal The blood pressure ranged around 150/90 during his hospital stay The blood Wassermann reaction was negative The first electrocardiogram showed the auricular fibrillation, and a second tracing was normal The roentgenogram during convalescence showed a mild prominence of the aortic knob and slight increase in markings in the right lung base Blood counts were normal except for the leukocytosis on entrance
- 1934—Age 63, a mild dysentery attack lasted about 10 days Stools were negative for amebas, and colon roentgenograms were normal Urine was negative Blood pressure was 200/100
- 1935—Age 64, during this year he developed a mild angina of effort Response to nitroglycerin was always prompt and he continued at work uneventfully The blood pressure remained around 190/90
- 1936—Age 65, the attacks of angina persisted and were present on less exertion The blood pressure remained elevated at 200/100 The electrocardiograms showed no change in pattern

1937—Age 66, the anginal attacks became much more frequent and the character of the pain was much more severe and lasting. The response to nitroglycerin became less prompt and the dose was increased from $\frac{1}{150}$ grain to $\frac{1}{100}$ and finally to $\frac{1}{60}$. The marked increase in the anginal syndrome strongly suggested an oncoming occlusion, which occurred in December.

The patient developed severe protracted pain in the chest radiating down both arms. Morphine ($\frac{1}{4}$ grain) had no effect and a second dose was still ineffective in controlling the pain. The blood pressure was 176/128 on admittance to the hospital. Oxygen therapy relieved his pain and anxiety materially. The electrocardiogram showed a right bundle branch block, the leukocyte count rose to 13,500, and the urine showed albumin and casts.

The patient lived 4 days after admittance. His blood pressure gradually fell from the initial systolic level to 176 and down to 90 on the last day of life. The chest was filled with moist coarse rales. The patient became stuporous and died suddenly.

Autopsy

The heart showed a left ventricular enlargement, weighing 560 gm, with extreme sclerosis of the aorta and coronary arteries. Thrombi were located in both the left and right main coronary arteries with extensive infarction of the left ventricle and the septum. Pericarditis (fibrinous) was also noted.

Both pleural cavities were obliterated by fibrous adhesions with marked scarring of both apices of the lungs. Bronchiectasis of the right lower lung was noted.

Other findings were cholelithiasis, diverticulosis of the colon, and varicose veins of the bladder.

Case IV

(Observed from 1933 to 1943)

1870—Mrs M. E., housewife, married, was born in Iowa. Her father died at 35 of an accident and her mother lived to the age of 88 to succumb to pneumonia. Her only sister had hypertension and apoplexy, dying at age 72.

1880—Age 10, she had measles, chickenpox and scarlet fever prior to this date.

1881—Age 11, onset of menstruation.

1889—Age 28, married (never pregnant).

- 1903—Age 33, appendectomy
- 1915—Age 45, fracture of the left ankle
- 1921—Age 51, routine examination because of indigestive syndrome revealed blood pressure of 135/85, negative urine and Wassermann reaction Roentgenograms of the stomach and colon were negative Achylia gastrica was found
- 1922—Age 52, menopause
- 1924—Age 54, removal of cervical polyp
- 1932—Age 62, she had a laparotomy for pelvic disease (operative procedure unknown)
- 1933—Age 63, mild angina of effort, fatigue, nervousness and distention of the abdomen were noted The blood pressure was 180/80, with a systolic apical murmur, and no evidence of cardiac failure The basal metabolic rate was plus 10 per cent, urine negative, Wassermann reaction negative, and blood counts normal The electrocardiogram was normal
- 1934—Age 63, her course was uneventful Blood pressure ranged from 140/80 to 210/90 She had one attack of "cystitis"
- 1935—Age 64, indigestive syndrome recurred with reappearance of angina of effort Graham-Cole roentgenogram of the gall-bladder showed stones Duodenal diverticula also were noted Blood pressure was 176/84 Electrocardiogram was unchanged Urine was negative
- 1936—Age 65, cholecystectomy was performed with uneventful recovery and marked improvement in gastro-intestinal symptoms and angina Blood pressure was 170/82
- 1937—Age 66, anemia was noted Gastric analysis showed no free acid The patient promptly responded to liver therapy Blood pressure was 190/90 A small postoperative hernia developed which was surgically repaired
- 1938—Age 67, course was unchanged Blood pressure was 200/100 Unexplained edema of the ankles developed Urine was negative Electrocardiogram was unchanged
- 1939—Age 68, blood pressure was 180/90 She was emotionally upset over her sister's apoplexy and death She had an unclassified dermatitis
- 1940—Age 69, her course was uneventful Blood pressure was 160/90
- 1941—Age 70, intermittent claudication developed The oscillometric readings on the left leg were zero Blood pressure was 180/90 During this year the patient had a mild cerebral thrombosis with apparently complete recovery
- 1942—Age 71, in February, the patient had an acute influenzal bronchitis lasting about a week Following this an arthritis of the

hands occurred, later involving the ankles and shoulders. Roentgenographic studies showed both hypertrophic and atrophic bone and joint changes. Blood pressure was 200/90. 1943—Age 72, the arthritis problem was persistent and gastro-intestinal symptoms became evident including anorexia, weight loss, mild nausea and distention. Roentgenographic examination of the stomach showed a carcinoma and later the tumor mass was palpable. Bone roentgenograms were negative for metastases. The weight loss continued although the blood pressure remained elevated around 180/80. The patient is still living.

Case V

(Observed from 1935 to 1937)

- 1878—Mrs. R. M., widow, housewife, was born in Chicago. Her father died at age 78 of pneumonia and her mother at 76 of influenza. One sister and one brother died of pneumonia.
- 1884—Age 6, measles
- 1897—Age 19, married
- 1898—Age 20, first pregnancy with no complications
- 1900—Age 22, second pregnancy with no complications
- 1902—Age 23, third pregnancy with no complications
- 1904—Age 25, fourth pregnancy with no complications
- 1905—Age 26, fifth pregnancy, stillbirth
- 1909—Age 30, sixth pregnancy, "blue baby"
- 1911—Age 32, seventh pregnancy with miscarriage at 4 months
- 1912—Age 33, eighth pregnancy, stillbirth
- 1913—Age 34, ninth pregnancy, miscarriage at 6 months followed by postpartum hemorrhage and then sepsis. She was hospitalized for 5 weeks and was said to be in "delicate health" following this pregnancy.
- 1923—Age 44, she was operated on for "inward goiter." Following this she was in a sanitarium for 6 weeks.
- 1925—Age 45, she was in a sanatorium for an illness classified as "sunstroke." Blood pressure was said to be 150 systolic.
- 1933—Age 53, a diagnosis of "albuminuric retinitis" was made. She was also told she had high blood pressure.
- 1934—Age 54, she had apoplexy followed by weakness of the right arm and leg. She also lost the sight of her right eye this year, said to be due to a hemorrhage into the retina.
- 1935—Age 55, vision in the left eye was lost. Subjective symptoms at this time were fatigue, poor vision, headaches, weakness of right arm and leg, nosebleed, and frequency of urination. Her blood pressure was 280/160. There was a systolic murmur at the apex and base of the heart. Ophthalmoscopic ex-

amination showed "bilateral optic atrophy with closure of both central retinal arteries" The blood counts showed a moderate anemia, the urine showed 2 plus albumin and a few casts The Wassermann reaction was negative The blood urea nitrogen was 22.2 mg The phenolsulfonphthalein test showed an excretion of 35 per cent and concentration of urine 1 012 with dilution to 1 001 The basal metabolic rate was minus 12 per cent The electrocardiogram showed a normal axis deviation with coronary defects in the T waves of Leads II and III The heart showed a marked left ventricular hypertrophy and a prominent aortic knob on the roentgenogram

1936—Age 56, urologic examination revealed a diverticulum of the bladder, stricture of the urethra, a functionless right kidney and a small contracted left kidney The blood pressure ranged around 260/150

1937—Age 57, progressively adverse course followed Her symptoms of fatigue, dyspnea and headaches became worse and edema gradually became evident She entered the hospital a few weeks prior to death in a state of marked cardiac insufficiency with edema, evidence of renal failure (blood urea nitrogen 71.4 and creatinine 4.70), and marked anemia She lapsed into stupor and coma

Autopsy

The heart weighed 540 gm, with marked sclerosis of both coronary arteries, and the thoracic and abdominal aorta The splenic artery showed unusual calcification

The right kidney was a lobulated hydronephrotic sac filled with cloudy fluid, with a hydro-ureter extending to the diverticulum of the bladder The right kidney was small with a thickened capsule, a sclerotic renal artery, and was clasified as "nephrosclerotic" histologically

Incidental findings were old ulcer scars of the stomach, a recent superficial gastric ulcer, a small cyst of the liver, and passive congestion of the abdominal viscera

COMMENT

The case records which have been presented are characteristic examples of the common, and some of the rarer, problems presented by patients with hypertensive vascular disease They show *persistent* elevation of blood pressure, and left ventricular enlargement is a common denominator to all Vascular disease is also a pertinent part of each individual record

Another common factor is the insidious onset, unmarked by any particular clinical episode. The course of each was measured in years, with a slow but inevitable evolution

Case I is a typical record in most respects, but exceptional with regard to the development of a relative aortic regurgitation. Hypertension is a common problem in the professional group, of which this lawyer was a common example. This particular patient was identified in his legal activity with a life insurance company and was well informed in life insurance statistics regarding blood pressure and albuminuria. While his course was practically symptom-free until the latter part, he was apprehensive and pessimistic about his future. When he developed the functional valvular incompetence, it apparently did not embarrass him until the further complication of coronary involvement was added. The coronary occlusion was exceptional because of the absence of pain and the dramatic collapse usually attending vascular thrombosis.

The terminal process was of interest because of the combination of both cardiac and renal failure. The final fall in blood pressure was coincidental with the development of the uremia, although the two processes may have been unrelated. The obstructive aspect of the midlobe of the prostate with the thickened bladder wall and the trabeculated bladder lining suggest that obstruction may have been a factor in the renal failure, although clinically no subjective symptoms suggested this possibility.

Another point was the multiplicity of the vascular pathologic processes—generalized arteriosclerosis, coronary sclerosis and thrombosis combined with pulmonary arteriosclerosis and thrombosis and terminally venous thrombi. The clinical and pathological record substantiates the older conventional terminology of cardiovascular-renal disease.

Case II represents the occurrence of hypertension at a much earlier decade of life, with a less complicated clinical picture. Subjectively, however, this patient presented a much greater intensity of symptoms almost from the beginning of her course and much greater hypertensive level. She has seemed remarkable in regard to the tenacity with which she has been able to carry on despite the height of the blood pressure, both systolic and diastolic, for so long a period of time.

Another interesting note is the negative result of the splanchnicectomy. The blood pressure fell to an extremely low level.

following the surgical procedure, but soon resumed the preoperative level and the result must be tabulated as completely negative. Her response to thiocyanate therapy was equally negative, either as to relief of subjective symptoms or objective results.

Presumptively this patient should have advanced coronary disease in view of the persistent cardiac pain, the distortion of the electrocardiographic pattern and the advent of myocardial failure. Her blood pressure level, however, has not been lowered to any great extent with this complicating factor. The renal aspects seem to have been a minor part of her clinical picture, and the vascular pathology clinically appears to be limited to the coronary circuit.

Case III shows a number of points of interest, particularly the dramatic coronary episode which terminated the clinical course so promptly. It is worthy of note that this patient began life with tuberculosis, and respiratory disease marked his whole life. It should also be remarked that the first cardiac episode was a transient auricular fibrillation which developed during the stress of the lobar pneumonia.

This patient was of unusual interest in the stage prior to his occlusion, as his angina gradually grew in intensity, in frequency, and the response to nitroglycerin diminished. It was obvious that acute coronary thrombosis was imminent, and equally obvious that prevention was impossible. Prompt hospitalization, oxygen therapy and sedation did not prevent a fatal outcome of the coronary occlusion.

Case IV is variant with regard to the termination by cancer of the stomach after a long record of hypertension and advanced vascular disease. The vascular involvement was clinically manifest first with angina and presumptively coronary sclerosis without evidence, however, of any occlusive phenomenon. The record then points to the peripheral arteries, with intermittent claudication, probably complete occlusion, and the development of a collateral circulation. Laterally, a disturbance of the cerebral circuit became manifest and the terminal phase of the patient's course has been distorted by seemingly unrelated medical entities—arthritis and carcinoma of the stomach.

The degree of arterial vascular involvement apparently has been severe as well as widespread, but the local lesions (coronary, peripheral, or cerebral) were not lethal and the patient

has been able to live out a normal life span, contrary to statistical averages

Case V is of significant interest in many respects. The record suggests that the hydronephrotic kidney had its inception in the puerperal sepsis of the last pregnancy. If it is assumed to have existed for some years, the patient apparently lived with a greatly decreased functioning renal parenchyma and finally succumbed when the remaining kidney failed to function. It seems reasonable to believe that this record supports the contention that uropathic disease is a causative factor of hypertension as well as chronic glomerulonephritis. The vascular involvement was both clinically and pathologically severe, but not lethal. The thyrotoxicosis, assuming the diagnosis was valid, apparently was unrelated to the hypertensive process.

CONCLUSIONS

The presentation of these five clinical records suggests the fundamental inadequacy of our knowledge of hypertensive vascular disease. The clinical records may be documented from month to month or year by year, as cardiac, vascular, or renal episodes are diagnosed with reasonable certainty or even predicted in advance on some occasions. Therapy may minimize subjective symptoms but the course of the disease seems unalterable and up to date no one has visualized the basic causative principle involved in this disease.

One may aptly compare the present state of our knowledge of hypertension with the concept of physicians of former years of "continued fevers." There was an era when fever was looked upon as a single disease entity, and therapy was directed toward decreasing the hyperpyrexia. Today a fever that cannot be classified as typhoid, miliary tuberculosis, subacute bacterial endocarditis or another well defined disease constitutes a challenge to the hospital resident and attending staff. Hypertensive vascular disease in all probability represents a number of specific disease processes in which the hypertension is a cardinal feature but less important than it is now generally esteemed. Therapy throughout two centuries has obviously been inadequate and our modern attempts seem of no greater effectiveness than those of our predecessors.

Experimentally, relatively little has been accomplished. One method (partial ligation of the renal arteries) has been success-

ful in producing an artificially sustained elevation of blood in animals. There have been a few well documented clinical and pathological records which are counterparts of this experimental method. The premature suggestion that this method is an adequate explanation of the so-called essential hypertension seems quite unwarranted.

Clinically, cardiac and renal failure are recognized with reasonable accuracy and localized vascular lesions of the brain, heart or extremities are usually well defined. Although the diagnostic accuracy of the profession has been increased, it would not appear that any real progress has been made to specify the underlying cause or causes of the disease process.

The future will undoubtedly reveal much to us regarding the mysteries of this problem, although there are many practical difficulties to obstruct productive research. This disease or group of diseases is one in which the course is measured in years, as a rule, and seldom does any one physician have a complete clinical document of an individual patient. The medical records are more often widely distributed in a number of physicians' files or hospitals and the final episode presented to a pathologist for evaluation represents only a minor portion of the complete history. A better correlation of records by the clinician, and particularly those in specialties for postmortem analysis, may prove of some help.

The final answer, however, is more likely to be found in some entirely new line of thought, as revolutionary as the discovery of bacteria or the solution of the deficiency diseases.

MITRAL STENOSIS

DON C SUTTON M.D.*

MITRAL stenosis is almost always the result of a benign endocarditis induced by acute rheumatic fever. It has been described as a congenital lesion, but in all the cases reported the lesion is either a complete atresia or so nearly so as to be incompatible with life. It appears possible that there may be an extremely rare congenital stenosis of the valve that is compatible with life. Mitral stenosis may also in rare instances be the result of atherosclerotic changes in the valve leaflets.

The inflammation of the valve which occurs in rheumatic fever is a nonulcerative lesion and therefore does not cause formation of thrombi. Embolic phenomena are absent. The valve changes are found principally on the edges of the cusps which are thickened and often adherent to one another. With the healing process the valves, particularly the edges, are thickened and as the scars contract become distorted and irregular. The adhesions become firm and further distort the valve. The chordae tendineae are often involved with thickening and loss of elasticity. The end result is narrowing of the mitral orifice to a varying degree and almost invariably there is enough irregularity of the valve edges to prevent complete closure, resulting in a concomitant valvular insufficiency.

Mitral stenosis diminishes the amount of blood expelled during each systole and results first in dilatation of the left auricle and stasis in the pulmonary venous bed, and ultimately in an increase of pressure in the pulmonary artery with hypertrophy and dilatation of the right ventricle. The increased pulmonary venous pressure causes pulmonary edema and dilatation of the venules. Dilated pulmonary veins often rupture causing hemoptysis. Because of the decreased amount of blood flowing into the left ventricle the pulse is small and increased in rate.

* Associate Professor of Medicine, Northwestern University Medical School; Attending Physician, Cook County and Evanston Hospitals.

From a prognostic viewpoint the most important observation is the degree of stenosis present. Helpful signs in its evaluation are (1) a marked mitral facies, namely flushed cheeks, flushed, slightly cyanotic lips and ear lobes, (2) the smallness and rapidity of the pulse, and (3) a mid-diastolic murmur.

COURSE AND PROGNOSIS

Illustrative Cases

CASE I—MISS B, now forty-four years of age, had her first attack of rheumatic fever at the age of nine years. At this time her parents were told that she had an injured heart valve. Two years later she again had an attack of rheumatic fever followed by chorea which lasted several months. As far as she knows the heart was not further damaged by these attacks.

After this attack she continued well for years. She attended a private school and a woman's college. After finishing college she led a moderately active social life always restrained by a solicitous mother. Her father died when she was twenty-five years of age and since that time she and her mother have been constant companions. After her father's death she spent some time every year at one of the European spas although she enjoyed excellent health.

While in Europe the panic of 1929 occurred and she returned home to find her income greatly reduced. She was much upset and consulted me because of palpitation and breathlessness. She was found to have a moderately high grade mitral stenosis and insufficiency but was well compensated and required no medication. Her heart was moderately enlarged to both the right and left, i.e., a typical mitral-shaped heart. At the apex was heard the typical pre-systolic murmur, a systolic murmur and a very much accentuated pulmonic second sound.

Beginning in 1935 through 1938 the patient reported attacks of what were called gallbladder colic. These attacks always occurred during a trip out of town. In the latter part of 1938 she was given a routine examination which revealed no change of her status. Two hours later she was seen because of another attack of "gallbladder colic." These attacks were then explained. Her liver was acutely enlarged to a hand's breadth below the costal margin and was painfully pulsating.

Her so-called colic, then, had been temporary attacks of right heart failure with the development of a relative tricuspid insufficiency. During 1939 these attacks occurred with increasing frequency and finally by the end of the year the tricuspid insufficiency became permanent.

Early in 1940 a permanent auricular fibrillation developed, the ventricular rate of which has been easily controlled by the administration of digitalis. During the entire period of my observation of her she has complained frequently of joint pains, at times accompanied with a low grade fever which makes one wonder if she still harbors a mild infection of rheumatic fever.

Since 1940 her cardiac reserve has very gradually but definitely diminished. The apex now extends almost to the axillary line and the right border extends 4 cm. to the right of the sternal line. There is now a definite mid-diastolic murmur which indicates a more advanced stenosis of the mitral valve. There are moist rales heard at the base of both lungs posteriorly. Also it is necessary to give her ammonium chloride and mercupurin at four- to six-week intervals to control the edema in spite of greatly decreased physical activity.

Recently, examination has revealed a very firm liver with less obvious pulsations, an enlarged spleen and a gradually increasing ascites. These changes in the liver and the onset of the ascites are due to progressive fibrosis in the liver following the prolonged passive congestion with a progressive obstruction of the portal vein.

This woman has run a course much better than the average in my experience. Economically, she has been able to lead a life that appears to be ideal for one with mitral stenosis. It is true that one occasionally sees such a patient who lives into the seventies, but in my statistics from the Cook County Hospital Cardiac Follow-up Clinic and my private practice the optimal duration of life in 95 per cent of cases of mitral stenosis is forty-five years for women and fifty years for men.

CASE II—This fifteen-year-old colored boy has been in my ward for the past five months. He entered the hospital because of a severe attack of acute rheumatic fever which lasted for three weeks. At ten years of age he had the first attack of rheumatic fever which left him with a mitral stenosis and insufficiency. When he first came into the ward he had a mitral stenosis of moderate degree and also a questionable insufficiency of the aortic valve. The latter lesion has become much more pronounced because of the infection which will be described.

When his convalescence from the rheumatic fever began he developed an abscess of a left lower molar, for which the tooth was extracted. Following the extraction he developed a septic type of temperature, with fever ranging as high as 103° F. This fever has continued to the present time. Repeated blood cultures have been negative, nevertheless we believe this to be a subacute bacterial

endocarditis He has had a moderate leukocytosis and a persistently high sedimentation rate

This case represents a not infrequent course, with repeated attacks of rheumatic fever ending ultimately in a frank bacterial endocarditis which ultimately will be fatal

CASE III—This young man, now twenty-four years of age, had his attack of rheumatic fever at twelve years of age from which he evidently developed a benign endocarditis of the mitral valve with mitral stenosis and insufficiency He was well until two weeks before entering the hospital three weeks ago, having spent the last five years doing moderately heavy work in a machine shop Five weeks ago he developed fever and red, painful, swollen joints

At the time of entrance he presented the findings typical of rheumatic fever The fever reached 103° to 104° F and was of the daily septic type Within a few days petechial spots were seen in the conjunctivae and in the soft palate The first blood culture revealed many colonies of a green-producing streptococcus

This case represents a frank bacterial endocarditis due to the organism most commonly found when bacterial endocarditis occurs as a complication in cases of old rheumatic valvular disease, namely the *Streptococcus viridans* This, unfortunately, is a frequent complication, occurring at any time after the initial valvular injury, so that bacterial endocarditis is seen in individuals ranging from ten to forty-five years of age Unfortunately on the whole this disease is always fatal In a large series we have records of six cases which recovered spontaneously There is an increasing number of reports of recovery following the use of the sulfonamide compounds but yet a pitifully small number in relation to the number of failures

CASE IV—This woman, aged forty years, has been a regular attendant in the Prenatal Division of the Cardiac Follow-up Clinic for the past twelve years When she was referred to the clinic she had a well developed mitral stenosis She is unable to give any history of an acute rheumatic fever, chorea or even frequent attacks of tonsillitis In fact, she was unaware of having any heart disease until she was referred to the Cardiac Clinic Nevertheless she had already borne five children and since she has been attending the Clinic has borne six more She still is well compensated although she has a more than moderate mitral stenosis

This woman is representative of a very large group of individuals having rheumatic heart disease who are or have been completely unaware of the condition until it is found as the result of a physical examination for another cause. For some reason these persons are unable to give a history that explains the onset of the valvular endocarditis, which may be due to a mild rheumatic infection that was overlooked or was later forgotten. Among 247 cases of mitral stenosis observed in the Prenatal Heart Clinic, only 32 per cent gave a history of rheumatic fever or chorea.

Pregnancy and Mitral Disease

There is considerable controversy as to whether the woman with mitral disease should marry and if she does should she bear children. Of course there is no question as to the advice to be given a young woman who has a high grade mitral stenosis or for some other reason is barely able to maintain a compensation. On the other hand, there is a large group of both sexes who, following an attack of rheumatic fever, enjoy excellent health for many years, say until thirty-five to forty years of age. In this group it is our observation that it is safe for women to marry and bear children. Among our group of 247 cases in the Prenatal Cardiac Clinic not a single patient died during pregnancy or labor. One died six weeks postpartum of bacterial endocarditis. During the same period 60 per cent of the women entering the hospital without prenatal care and decompensated died. It is then evident that the pregnant woman with mitral stenosis requires special care, but with such care fares as well as her more healthy sisters.

It is also stated by some authorities that, although the woman with mitral stenosis may not die during pregnancy or labor, when such women bear children their life span is shortened thereby. From the general heart clinic we compiled a series of 118 patients who had no pregnancies, and one of seventy-nine patients with one or more pregnancies. Between the ages of twenty and thirty years, 10 per cent of both groups died. Between the ages of thirty and forty, 16 per cent of the nonpregnancy group died and only 10 per cent of the pregnancy group died. Between forty and fifty years, 27 per cent of the nonpregnancy group died whereas only 17.7 per cent of the pregnancy group died.

Other Factors Affecting the Course and Prognosis

The course and prognosis of mitral stenosis are difficult to discuss in general terms as each individual case presents its own problems. Practically every case of mitral stenosis is combined with mitral insufficiency, however, the mitral stenosis is the lesion having the greatest mechanical effect upon the circulation. With increasing narrowing of the mitral orifice there is a progressive pulmonary congestion. This back pressure in the pulmonary veins leads to diminished aeration of the blood with cyanosis and dyspnea. Pulmonary vessels may rupture causing blood-stained sputum or even frank and at times fatal hemorrhage. Increased pulmonary vessel pressure increases the load upon the right ventricle, which may fail with resultant peripheral edema with or without a relative tricuspid insufficiency. These symptoms may be primarily the result only of the narrowing of the mitral orifice and their severity depends upon the smallness of the opening.

The effects of mitral stenosis within the limits of extreme narrowing are greatly influenced by the *degree of damage the myocardium has suffered* from the rheumatic infection. Every attack of rheumatic fever causes some damage to the heart muscle. If this is severe the heart may be unable to cope with even a mild stenosis, or if the damage is little then a severe stenosis may be tolerated for many years.

The course of mitral stenosis is further influenced by the *degree of injury to the pericardium* by the rheumatic infection. Besides changes in the endocardium and myocardium, inflammation of the pericardium is a not infrequent lesion. This lesion may vary from a slight fibrinous pericarditis to one involving the whole pericardial sac. This inflammation may further result in a pericarditis with effusion. If the patient recovers there is often left a varying number of adhesions between the visceral and parietal pericardium even to the extent of complete obliteration of the pericardial cavity. Moderate to extensive adhesions interfere severely with the mechanical efficiency of the heart.

Exercise and work exert an important influence upon both the course and prognosis of mitral stenosis. For many years we have limited the exercise and work of children and adults under twenty-five years of age only upon evidence of overexertion, as dyspnea or edema of the extremities. We have found that a

large number of young adults can continue strenuous sports as boxing, swimming, tennis, football and basketball without harm. We believe those individuals who can do strenuous exercise without adversely affecting their cardiac reserve are building an hypertrophy of the heart muscle that gives them a reserve to help compensate for the valve defect in later years. However, when one observes the effects of hard work over a period of years it is evident that strenuous work should be limited to those under possibly twenty-two years and certainly under twenty-five years of age.

When no other cause intervenes, most laborers who have mitral stenosis suffer their first decompensation at about thirty-five years of age. This is at least true for the type of patient we have in the Cook County Hospital. Those of more sedentary occupations carry on over a longer period.

The child with mitral disease should be trained in the lighter occupations and told to cease strenuous exercise between twenty and twenty-five years of age.

Infections varying from ordinary "colds" to the more severe ones are always likely to affect the myocardium adversely. Patients with even mild infections should be put to bed promptly and their convalescence prolonged until one is sure the heart has recovered completely from any adverse effects of infection. Acute infectious disease is also very likely to be the forerunner of an attack of acute rheumatic fever or even a bacterial endocarditis.

Bacterial endocarditis usually due to the *Streptococcus viridans* is always a potential complication of rheumatic heart disease and is a frequent cause of death in such cases.

The onset of a cardiac irregularity, especially an auricular fibrillation, may be the precipitating cause of failure in mitral stenosis. Repeated attacks of *paroxysmal tachycardia* of auricular origin often precede the onset of an auricular flutter or auricular fibrillation. Such attacks are usually of short duration but if prolonged for several hours may lead to decompensation.

Auricular flutter occurs most commonly in mitral stenosis and if not paroxysmal and of short duration leads to heart failure. *Auricular fibrillation* like flutter is usually a complication of mitral stenosis, this lesion being the cause in 70 to 80 per cent of the cases. Auricular fibrillation may occur in paroxysmal form lasting a few minutes to days. When it becomes a perma-

nent irregularity it almost always results in acute heart failure with the usual symptoms of dyspnea, cyanosis and edema. Without digitalis therapy, auricular fibrillation with mitral stenosis would almost invariably cause early death. The slowing of the ventricular rate by digitalis therapy leads usually to compensation and in many cases patients may continue in a relatively good state of health for a number of years. We have a number of such patients who have attended the clinic some ten to fifteen years, and during this time have been able to maintain themselves at work. In auricular fibrillation the auricles assume permanently the position of diastole. In such distended auricles mural thrombi frequently form, especially in the auricular appendages. Emboli breaking from these thrombi may be the cause of cerebral embolism, pulmonary embolism or emboli to the periphery, causing gangrene of an extremity or infarction of an organ as the kidney or spleen. At autopsy multiple, clinically unrecognized pulmonary emboli are often found.

SUMMARY

The prognosis of stenosis of the mitral valve depends upon

- 1 Age. Very few individuals live beyond the age of fifty years.

- 2 The degree of stenosis present. The smaller the mitral opening the greater the mechanical difficulty of the heart in maintaining an adequate circulation.

- 3 The amount of permanent damage to the heart muscle lessens the ability of the heart to compensate for the stenosis.

- 4 Adhesive pericarditis depending upon its extent greatly hinders the contractile power of the ventricles and interferes as well with the filling of the auricles.

- 5 The demands made upon the heart by work are extremely important in the maintenance of compensation. In youth, exercise within limits of tolerance may serve to build a heart muscle hypertrophy which furnishes a reserve for later life. Continued strenuous exercise or work leads to earlier failure than do more sedentary occupations.

- 6 Infectious diseases may interfere with compensation in mitral stenosis as the result of toxic injury to the heart muscle, as a precipitating cause of a recurrent rheumatic fever, or as the cause of a bacterial endocarditis. Bacterial endocarditis usually

due to the *Streptococcus viridans* is a frequent fatal complication of mitral stenosis.

7 A cardiac irregularity, such as paroxysmal tachycardia, auricular flutter or auricular fibrillation, may be the cause of acute heart failure. Paroxysmal tachycardia is the least frequent cause. Auricular flutter is the next most frequent and the most serious in its effects upon the circulation. Auricular flutter is the most frequent permanent irregularity in mitral stenosis.

HEART BLOCK*

ITALO F. VOLINI, M.D., F.A.C.P.†

THE extensive use of electrocardiography has greatly expanded the subject of heart block. In fact, by far the major number of diagnoses of heart block in the minor degrees of this disturbance of conduction is recognized by this mode of examination alone. Even what may be considered major and very serious types of heart block, such as bundle branch block, are often revealed only by the graphic registration. Recognition by clinical signs and symptoms particularly in the presence of a regular cardiac rate and rhythm is practically impossible. Associated evidence even when present is meager, equivocal, indecisive and requires the aid of electrocardiography to establish a definite diagnosis.

Heart block defined is an arrhythmia involving the conducting mechanism of the heart, with inability to transmit the impulses in a physiologic manner from the auricles to the ventricles. Auriculoventricular heart block implies an extensive range of disturbances varying from the simple increased functional activity of vagal tone producing a mild delay in impulse transmission to the total inability of the conducting system to pass on stimuli from the auricle. In the former the administration of atropine clears the delay completely, while in the latter the use of a long list of potent drugs usually effects no change.

COMPLETE HEART BLOCK

While in certain rare cases of complete heart block, the ventricles may contract more rapidly than the auricles, the classical picture of complete heart block shows a very slowly acting ventricle. This common type, although not often encountered

* From the Cook County Hospital and the Department of Medicine, Loyola University School of Medicine.

† Professor of Internal Medicine and Chairman of Department of Medicine, Loyola University School of Medicine, Senior Attending Physician and Director of the Department of Medicine, Mercy Hospital—Loyola University Clinics.

in clinical practice, is frequent enough to be readily recognized because the clinical symptoms and manifestations present a clear-cut typical pattern

Thus, Mrs I K, a white woman aged sixty-two years, was admitted to the Volini Medical Service at Cook County Hospital on April 19, 1943, her third entrance in two years. She complained of dizzy spells which occur at anytime but more frequently on standing or exertion, rather than at rest. Syncopal attacks often follow the periods of vertigo. The patient does not know what happens to her while unconscious, although she describes her state at these times as paralyzed. The extremities jerk at times during the episodes of unconsciousness. Dyspnea is present only on effort. Nocturia two or three times a night is described. There was a history of palpitation two years ago, but this subsided with the onset of the present complaint. The complete history otherwise has no direct bearing on the present illness or on the presentation of this symptom complex which will be discussed from the clinical and laboratory evidence.

The *physical examination* has the following positive features which directly concern our subject of complete heart block. The general appearance of the patient is alert, not presenting an acute illness. She rests quietly on one pillow, not complaining very much. The pulse rate is 38 per minute. The apex rate with the stethoscope is 38. The blood pressure is 240 systolic and 80 diastolic. The eye grounds show tortuosity and silver streaking of the vessels with nicking, but no old or new exudate or hemorrhages. The heart is enlarged with the left border 12 cm. to the left of the midsternal line, physical evidence which is corroborated by the 2-meter chest film. The heart rate is slow, 38 per minute at the apex. The sounds are good, slow, strong and regular with a systolic murmur found at the apex with another systolic murmur which is louder over the aortic area and transmitted up into the neck vessels. Auricular activity can be visualized in the external jugular veins during the interventricular soundless period, but the evidence of sounds audible by use of the stethoscope produced by the contraction of the auricles cannot be detected. Auricular contraction can be seen by the fluoroscopic examination while the ventricles remain immobile. The clinical diagnosis is definitely indicated by

this classical pattern of complete heart block occurring in coronary arteriosclerotic heart disease

The *electrocardiogram* shows the auriculoventricular dissociation with a regular auricular rate of 75 per minute, while the rhythmic ventricular autonomic rate is 40. A somatic tremor distorts the graph especially the P (auricular) waves, but the neuromuscular distortion can be neutralized by viewing through the partially closed lids of the observer, which render the auricular waves clear, prominent and more evident. Left axis deviation and intraventricular conduction deformity are also noted in the complete graph (Fig. 1)

While no complaints were manifested while the patient was at rest in the ward, *vertigo* was present on slight activity. This demonstrated the well known fact that despite the slow ventricular activity, an adequate minute volume output is maintained approximately equal to the output during normal ven-

Fig 1—Complete heart block with auricular ventricular dissociation or idioventricular rhythm

tricular rates of 72 to 80, sufficing for metabolic demands at rest. This is accomplished because of the greater filling during diastole, the more complete ventricular emptying, with the high systolic pressure. During physical activity or because of other demands for increased output, the secondary autonomic center of impulse production for ventricular control becomes exhausted. Thus ventricular standstill occurs, which results in cerebral anemia and the Stokes-Adams syndrome appears. These episodes were very vividly indicated by the patient's story. These seizures were described as both apoplectic and epileptic.

Recovery ensued as a result, first, of resting of the secondary center for the idioventricular rhythm control, so that metabolic action could be resumed, and secondly, of irritating metabolites which produced contraction of the ventricles and thus improved the anoxemia, focally, locally and generally. This improvement results from oxygen and blood movement.

HEART BLOCK

Drug Therapy in Complete Heart Block

In unpublished studies made for the purpose of evaluating the effect of various drugs used to increase the ventricular rate in complete heart block of coronary arteriosclerotic disease origin, none was found effective. They included atropine, epinephrine, ephedrine, amphetamine, nitroglycerin, barium chloride, thyroid extract, metrazol, nikethamide and the xanthine group of compounds. The occasion did not arise in the present case for the intracardiac injection of epinephrine. The patient had no attacks of ventricular asystole causing Stokes-Adams seizures during her stay in the hospital. While complete heart block may rarely be temporary, as when induced by digitalis and rheumatic fever, auriculoventricular dissociation is much more of an organic permanent variety. A few weeks to several months waiting time distinguishes and cures the temporary form.

After determining the ineffectiveness of these drugs to improve the ventricular rate, vagal stimulation by carotid sinus pressure was attempted to see if further slowing would occur. The action was negative. However, ventricular standstill was induced by the subcutaneous injection of 10 mg of mechoyl, the cholinergic parasympathetic stimulant. The action was immediate. Fortunately, atropine sulfate injection restored the ventricular activity before intracardiac injection of epinephrine was necessary. Digitalis does not aggravate an idioventricular rhythm and can be and should be prescribed when indicated in complete heart block. While complete heart block may rarely be temporary, as when induced by digitalis and rheumatic fever, auriculoventricular dissociation is much more commonly encountered on a permanent basis from a vascular origin. This results from the closure of the blood supply of the auriculoventricular node and the auriculoventricular bundle which receives blood almost entirely from one special branch of the posterior descending division of the right coronary artery. Occasionally, calcification of the interventricular septum at the site of the auriculoventricular bundle is also present.

In very rapid supraventricular stimuli such as occur in auricular fibrillation, auricular flutter and extremely rapid auricular paroxysmal tachycardia, auriculoventricular heart block is, in reality, a physiological mechanism. Under these conditions, stimuli are received at the auriculoventricular node faster than

the node or bundle can normally function as a conducting system Only those stimuli which this upper physiological limit can accept, pass through, and are thus transmitted along the conducting system The ventricles then respond This upper limit is approximately 190 The grade of block can be readily recognized as a rule by the electrocardiographic tracing

FIRST DEGREE HEART BLOCK (DELAYED CONDUCTION TIME)

The simplest type of heart block is recognized by graphic means alone The commonest causes are digitalis, rheumatic fever, and arteriosclerotic coronary disease (Fig 2), although

Fig 2—First degree heart block in coronary arteriosclerosis

Fig 3—First degree heart block seen in Roger's disease No digitalis was used A large interventricular septum defect was found postmortem

Fig 4—First degree heart block The P-R interval is prolonged to 0.28 seconds and is the result of the action of digitalis The digitalis effect is noted on the S-T segment.

it may result from congenital heart lesion (Roger's disease, Fig 3), asphyxia, diphtheria, uremia, severe liver disease and excessive vagal stimulation This type of auriculoventricular blocking is called first degree block and results from a simple retardation of the impulse in its transmission to the ventricles This sluggishness is manifested by a prolongation of the P-R interval beyond the usual upper limit of the normal average

time of two-tenths of a second. One of the most frequent signs of digitalis activity is first seen in this prolongation of the P-R conduction time (Fig. 4)

Diagnostic Importance of Prolongation of P-R Interval in Rheumatic Fever

The P-R interval prolongation measured in the electrocardiogram acquires particular significance in its relation to rheumatic fever (Fig. 5). It is commonly present in rheumatic carditis, whether the major effects are valvular, myocardial, or pericardial. While in the younger child the valvulitis (in the absence of pericarditis) presents the focalizing signs, the electrocardiogram through the P-R interval prolongation shows the acute rheumatic myocarditis. The evidence of myocarditis, of course, is usually found in all of the symptoms and signs and associated laboratory evidence. However, in the young adult in his first attack of rheumatic polyarthritis, the evidence of valvulitis frequently never develops and the importance of the P-R interval prolongation is particularly significant of acute rheumatic myocarditis. The child develops valvulitis because of the vascularity

Fig. 5—P-R interval prolongation noted in rheumatic myocarditis

of his valves. Aschoff nodules develop close to small blood vessels. Adults possess avascular valves, hence the absence of rheumatic valvulitis during the initial rheumatic attack in adulthood. In both child and adult, however, the widespread signs of rheumatic fever are found in the rheumatic myocarditis presented clinically, but often graphically, and occasionally graphically alone, in the prolongation of the P-R interval. This evidence clears eventually and in practically all patients it disappears entirely as one would naturally expect from the development of the microscopic scar of a healed Aschoff nodule in the myocardium.

The diagnostic importance of the prolonged P-R interval is also appreciated in the presence of vague mild muscular pains without pronounced signs of the systemic evidence of rheumatic fever such as elevated temperature and pulse rate, anemia, in-

creased sedimentation rate and raised white blood count. Again, rheumatic fever without pronounced focal cardiac signs and symptoms flares up during or shortly after acute infectious diseases, such as scarlet fever, measles, upper respiratory disease with acute otitis media, and pneumonia, and the P-R lengthening aids in the diagnosis of rheumatic myocarditis. An occasional case of mono-articular arthritis of acute variety can be diagnosed as of rheumatic fever origin by the recognition of P-R interval prolongation beyond the normal two-tenths of a second.

Thus Mrs M M, a colored woman aged twenty-six, was admitted April 23, 1943, with a history of fever, pain, throbbing and swelling with tenderness of the left knee of two weeks' duration. She had a similar episode with the left elbow, one month prior to entrance to the hospital. She was a known diabetic for five years, the disease being controlled by 40 units daily of protamine zinc insulin. She was in the fourth month of her fourth pregnancy. Moderately severe secondary anemia existed. While she was under observation during the first few days a systolic murmur appeared at the apex. All serologic data including complement fixation for Neisserian infection as well as smears and aspiration of the knee joint were negative. While infectious arthritis appeared as the most probable conclusion, a bifid or mitral P wave was noted as well as a P-R interval of 0.28 of a second. This on subsequent electrocardiograms reached 0.34 of a second. Salicylates and bed rest with local heat to the knee produced gradual improvement, although the patient was in bed for three months. Complete restoration of the knee joint occurred with complete disappearance of all evidence of cardiac involvement, including the electrocardiographic signs. The patient was discharged to the prenatal and diabetic clinics for further care.

SECOND DEGREE HEART BLOCK (PARTIAL HEART BLOCK)

In second degree heart block the defect in conduction is manifested by an occasional failure of the ventricle to contract due to lack of the impulse to get through from the auricle to the ventricle. This may occur as a progressive prolongation of the P-R interval until it is so lengthened that a dropped ventricular beat occurs. This is known as a *Wenckebach periodic beat* (Fig 6) and is most commonly encountered in rheumatic myocarditis.

In partial heart block, as second degree heart block is known,

HEART BLOCK

increasing difficulty is noted in the ability of impulses to get through the conducting system. While ready recognition is easily attained by graphic means, clinical diagnosis can be ascertained without undue difficulty by combining auscultation with palpation of the pulse. In the higher grades of partial heart block the dropped beat may occur regularly, appearing at every eighth, seventh, sixth (and so on) interval of ventricular activity. It is then known as a 9:8 block, or 8:7 block, and so

Fig 6—Progressive prolongation of the P-R interval until a ventricular contraction does not occur. Produced by rheumatic fever and known as the Wenckebach phenomenon.

forth. However, in rheumatic fever, in digitalis overaction and in coronary disease, dropped beats may recur at very irregular and unpredictable intervals. Then graphic registration may often be necessary.

BUNDLE BRANCH BLOCK

In the early experimental work on animals, right and left bundle branch block was described in the resulting electrocardiograms obtained upon the section of the respective branches of the auriculoventricular bundle. Complete reversal of interpretation has, however, resulted from experimental and clinical evidence within the last decade. Bundle branch block is an electrocardiographic diagnosis. While suggested by split or slurred first or second sound with or without gallop rhythm, graphic registration is necessary. Often, no clinical evidence whatever is presented and it becomes an accidental diagnosis because the electrocardiograph was employed. It is a symptom and not a disease. While most often encountered in the arteriosclerotic processes in the coronary artery system, rheumatic fever and rarely syphilis and congenital heart lesions are the most common known agents producing this type of block. Hypertension with left ventricular strain often accompany or precede the development of the arteriosclerosis of the coronary arteries, particu-

larly where left bundle branch block is found. Acute coronary occlusion is a frequent cause of this type of conduction disturbance.

Histologic studies indicate extensive fibrotic lesions invariably present in both branches of the auriculoventricular bundle in either right or left bundle branch block. Considerable dam-

Fig 7A—Mrs I S Left bundle branch block concordant seen in June, 1937

age, however, may be present without pronounced changes or only minor evidence in the electrocardiogram being apparent. Conversely, considerable distortion may be present such as classical bundle branch block in which only a small artery is involved or a small focal lesion exists in the appropriate bundle. Classical bundle branch block, often referred to as *concor-*

damt type, characteristically shows the main QRS deflection opposite to each other in Leads I and III with a duration greater than 0.1 second and their respective T waves opposite to the main QRS deflection. Atypical or incomplete types recognized as *discordant* graphs do not possess the characteristic T wave conformity. Wilson has directed attention to the intraventric-

Fig 7B—Mrs. I. S. Electrocardiogram in February 1943

ular block with the sharp high R wave in Lead I followed by the wide slurred S wave. Wolf, Parkinson and White describe the clinical syndrome of attacks of paroxysmal tachycardia with normal ventricular complexes occurring in classical bundle branch block showing short P-R intervals.

Serious generalized cardiac disease is usually indicated in the presence of the various types of bundle branch block, espe-

cially in the classical variety Nevertheless, reasonably good health can be expected in many patients for many years The outlook is less favorable in those developing the evidence during an acute coronary artery occlusion producing the symptomatology and evidence of acute myocardial infarction Many exceptions are encountered to this general rule, however

Fig 8—Mrs J P Left bundle branch block concordant, April 29, 1938
Patient active and continuing household duties, September 6, 1943

Figure 7 shows the left bundle branch block found in Mrs I S at the age of forty-seven years in 1937, and again her graph six years later with reasonably good health and almost no restriction of her physical activity in ordinary household activities and duties

Figure 8 shows the graph of Mrs. J P, aged fifty-one years,

taken on April 29, 1938 Classical left bundle branch block with concordant graph is seen She today cares for her household, but is restricted somewhat in her more strenuous activities

in Lead I and intraventricular conduction deformity with wide S pattern respectively

The observation must be made that complete consideration of symptomatology and all collateral evidence is frequently necessary to determine both the etiologic as well as the prognostic

Fig 10—Mrs A F, aged fifty-three years Bundle branch block with wide S pattern in Lead I

HEART BLOCK

and therapeutic implications. Etiologic diagnosis, subjective and objective symptoms together with the electrocardiogram will frequently determine prognosis and therapy in the many and various types of auriculoventricular block.

Occasionally, the evidence presented of the heart's ability to withstand function strain and of good cardiac muscle reserve

Fig 11-J H., aged sixty-three years. Wide S pattern with intraventricular conduction deformity

far outweighs the seriousness of electrocardiographic signs of auriculoventricular blocking. Nevertheless, sudden death occurring in a patient with minimal electrocardiographic variation, the importance of which has been minimized, is, to say the least, very disturbing to the conscientious clinician.

SYPHILITIC AORTITIS AND ANEURYSM*

AARON ARKIN, Ph D, M D, F A C P †

CARDIOVASCULAR SYPHILIS IS PREVENTABLE

SYPHILITIC heart disease is today the only form of heart disease which is preventable. A more general recognition of this fact will lead to a careful search of all patients infected with syphilis for the early manifestations of this most fatal form of the disease. A diagnosis in the primary seronegative stage by darkfield examination, followed by two years of proper treatment, would prevent at least 90 per cent of cases of cardiovascular syphilis.

I wish in this clinic to discuss the pathology and diagnosis of syphilitic aortitis. Syphilis is responsible for about 20 per cent of cases of chronic cardiac disease found in adults. About one-fifth of all persons who acquire syphilis develop cardiovascular disease. The average length of time from infection to the onset of symptoms is about fifteen years. In luetic aortic regurgitation the average latent period is twenty years, in aneurysm twenty-two years. At necropsy we find that 75 per cent of persons with visceral lues have an aortitis. It is therefore obvious that many of these individuals do not develop clinical evidence of heart disease, and are not diagnosed during life. We shall emphasize the methods at our disposal for the early diagnosis of uncomplicated syphilitic aortitis.

SEX AND RACE INCIDENCE

There is a marked preponderance of the male sex in the entire picture of syphilis of the heart and aorta. About 80 per cent of the patients are males, yet there is no marked difference in the frequency of luetic aortitis in the two sexes. In females the disease takes a more benign course. The severe supravalvular forms

† Professor of Medicine and Chairman of Department of Medicine, Cook County Graduate School, Associate Professor of Medicine (Rush), University of Illinois College of Medicine, Attending Physician, Cook County and Mt Sinai Hospitals, Staff, Wesley Memorial Hospital

with aortic regurgitation, stenosis of the coronary ostia, and aneurysm are much more common in men

Syphilitic heart disease is about four times as frequent in the Negro as in the white. Aneurysms are twice as common as in the white race. The greater number of hard laborers, high incidence of hypertension, and more frequent neglect of proper therapy may explain this difference. I believe that there is a more marked involvement of the media with more extensive necrosis in the colored race. While aneurysm is rare in white women we find it not infrequently in Negro women.

PATHOLOGY OF SYPHILITIC AORTITIS

Syphilitic aortitis is the basic lesion from which the manifestations of cardiovascular syphilis develop. It leads to aneurysm formation, widening of the aortic ring with separation of the cusps at the commissures and aortic regurgitation, and stenosis of one or both coronary ostia.

Luetic infection usually occurs in the twenties, yet the highest incidence of symptoms due to aortitis is near the forty-fifth year. The reason for this long latent period of twenty years is the very slow progress of the chronic inflammatory process which begins in the vasa vasorum of the adventitia and media. These small vessels undergo obliterative changes which furnish partial anaerobic conditions for the growth of the spirochetes in the media. There is an infiltration by round and plasma cells. The elastic fibers are destroyed by the development of miliary gummas. The destructive and inflammatory changes in the media lead to intimal wrinkling and puckering. The inner surface of the aorta becomes wrinkled and depressed by small and large fibrous scars of pinkish or white color. Atheromatous changes are often combined with the luetic aortitis in an amount increasing with age. The mouths of the large branches of the aorta, such as the innominate, carotid, and subclavian, are often fibrosed and greatly constricted or almost occluded. Thus stenosis of the ostia of the large arteries is of great value in diagnosis, leading to pulse differences, thrills and murmurs along the course of the vessels. Sometimes there is a complete absence of the pulse in one or more large arteries.

ANEURYSM FORMATION

As the aortic wall (in some cases also the innominate, carotid, subclavian or other large artery) loses its elastic layer the wall

becomes weakened. It stretches under the influence of the blood pressure. If the mesaortitis is widespread there may be a diffuse dilatation of the ascending, arch, descending or entire thoracic aorta. When the destruction is limited to a small area a saccular aneurysm may develop. Such aneurysms of the thoracic aorta are practically all luetic, whether atheromatosis be present or absent. Multiple aneurysms of the thoracic aorta are quite common.

Aneurysms occur in about 20 per cent of cases of syphilitic aortitis. They are most common in the ascending aorta and arch, and decrease in frequency toward the bifurcation. They tend to occur along the path which receives the impact of the blood column. This pathway runs in the middle of the anterior wall of the supra-avalvular portion, then to the right in the ascending, horizontally in the arch, and along the posterior left aspect of the descending arch, and in the middle of the posterior wall of the descending aorta. They may erode the spine, ribs or sternum.

We shall see that the demonstration of a widening of any part of the thoracic aorta is the earliest diagnostic sign of syphilitic aortitis. Such a widening can often be found before the development of aortic regurgitation, aneurysm, or angina pectoris. Syphilitic aortitis without dilatation of the aorta, regurgitation, or coronary stenosis cannot be diagnosed clinically.

When the orthodiagraphic measurement of the aorta exceeds the normal values, syphilitic aortitis must be suspected. This is especially so when the patient has a positive serologic test, Argyll-Robertson pupils, absent patellar reflexes, or any other evidence of lues.

Hypertension, rheumatic aortic regurgitation, isthmus stenosis, or thyrotoxicosis may lead to increased cardiac force or output with moderate widening of the aorta. With old age the aorta elongates, the arch rises and the vessel becomes more tortuous. There is evidence of atheromatosis, and the process is quite uniform. These conditions can usually be distinguished from luetic aortitis.

Aneurysm may be caused by bacterial emboli in bacterial endocarditis. It is very rare in rheumatic fever. Periarteritis nodosa, suppuration, tuberculosis and trauma are rare causes. Aortic rupture or dissecting aneurysm is usually the result of cystic media necrosis, first described by Erdheim. Abdominal aneurysm may be due to arteriosclerosis.

AORTIC REGURGITATION

Perhaps the most important pathologic change is aortic regurgitation. This is found in about 75 per cent of the cases diagnosed clinically, and in about 30 per cent of cases of luetic aortitis at autopsy. Syphilis has a special affinity for the sinuses of Valsalva and the aortic ring. The increased strain upon this region caused by the closure of the aortic cusps in diastole is a factor in producing the stretching of the ring. The cusps become thickened at the commissures and are separated from each other. No vegetations are produced, hence there is never a stenosis of the aortic ostium. The ring is stretched, the cusps are too small to close the lumen in diastole and regurgitation results. There is later a regurgitation at each of the commissures, and in the center of the lumen.

Syphilitic aortitis, therefore, causes only one valvular lesion, aortic regurgitation, never a stenosis. Rarely, syphilitic pulmonary arteritis causes a pulmonary regurgitation. The mitral and tricuspid valves are not affected. With regurgitation there is a progressive dilatation and hypertrophy of the left ventricle, often leading to great cardiac enlargement. The average length of life is about three years.

STENOSIS OF THE CORONARY OSTIA

Another important change is stenosis of the ostia of the coronary arteries. This is a very frequent finding, a part of the aortitis in the sinuses of Valsalva. It leads to anoxemia of the heart muscle with angina pectoris. The anginal attacks are usually of long duration. The T wave is often negative in Leads I and II of the electrocardiogram. Myocardial failure which reacts poorly to all medication is the end result. The stenosis is so gradual that one ostium may be totally occluded without producing clinical symptoms or any gross myocardial changes. During the years that elapse there is plenty of time for the collaterals to enlarge so that the heart muscle gets its nourishment from the other coronary. When both coronaries are affected the heart may be unable to undergo much hypertrophy. The heart muscle may still receive some blood supply from the thebesian channels, or from anastomoses between the coronaries and vasa vasorum or bronchial arteries.

Sometimes the coronary ostium is covered by a small flaplike thickening of the intima. The presence of an aortic regurgita-

tion reduces the blood flow in the coronaries still further by lowering the diastolic blood pressure. Sudden death is not uncommon in such cases of aortic regurgitation with stenosis of the coronary ostia. In very rare cases a supernumerary vessel may furnish blood to the myocardium.

It often appears as if the stenosis of the coronary ostia protects them against atheromatosis by reducing the blood flow and pressure in these vessels. The arteries themselves are not affected in syphilis, hence coronary thrombosis with infarction

FILED

Fig 12—Early syphilitic aortitis, with characteristic convex prominence of the ascending aorta. There was a typical tambour aortic second sound, heard best in the second right interspace. There was no regurgitation, hence the heart is normal in size. The Kahn test was positive.

is uncommon. When it does occur it is usually the result of sclerosis or subintimal hemorrhage.

The heart muscle is only rarely affected by syphilis. Seldom is a gumma or diffuse syphilitic myocarditis found. In the bundle of His it may lead to heart block. In a papillary muscle rupture may occur. The fibrous changes found in older luetic individuals are more readily explained as a result of arteriosclerotic nonluetic coronary disease, or ischemia of the muscle from the stenosis of the ostia.

It must be emphasized here that aneurysm alone does not cause cardiac enlargement, regardless of its size. In the absence of aortic regurgitation, coronary disease, hypertension or other cause, the heart remains normal (Figs 13, 15, 20) Aneurysms of the supra-auricular portion of the aorta may rupture into the pericardial sac, causing death from heart tamponade Syphilitic aneurysm is not likely to lead to a dissecting aneurysm because of the inflammatory changes in the media and adventitia It often compresses the trachea, left bronchus, esophagus, pleura, or lung It may rupture into any adjacent structures

DYSPHAGIA AND LEFT HEMOTHORAX

I have in the past few months seen three cases of aneurysm of the arch with compression of the esophagus and marked dys-

Fig 13

Fig 14

Fig 13—Aneurysm of the arch of the aorta with marked compression and displacement of the trachea and esophagus. The patient had marked dyspnea, an asthmatic wheeze cyanosis and dysphagia. He could not even swallow liquids. There was no aortic regurgitation, hence heart is normal in size. The diagnosis was made clinically from the history and physical examination

Fig 14—Same patient as Figure 13 with barium in esophagus. Note the marked displacement of the esophagus to the right with a complete occlusion. The patient died three weeks later of a perforation of the aneurysm into the esophagus (autopsy)

phagia (Figs 13, 14, 15, 20) In two of the cases swallowing became impossible. One patient died of perforation into the esophagus, another of tracheal compression (Figs 14, 15)

We have had five cases of aneurysm of the descending aorta with dysphagia. In three there was also erosion of the spine. Four years ago I had under observation a patient with a syphilitic aneurysm of the right subclavian artery with marked erosion of the right clavicle, and clubbed fingers of the right hand (Fig 25)

We have had five cases of aneurysm of the arch and descending aorta with left hemothorax. In one there was an accompany-

Fig 15—Aneurysm of the arch of the aorta with marked dysphagia. Note the marked dilatation of the aortic arch, with an aneurysm of the descending portion pointing to the right and occluding the esophagus. There was no aortic regurgitation. The diagnosis was made clinically from the history of dysphagia, a tracheal tug, and visible pulsation in the left sternoclavicular region. The case is quite similar to that in Figures 13 and 14. Both were in my ward at the same time.

ing atelectasis of the left lung from occlusion of the left bronchus (Figs 22, 26, 27). I have for several years recognized this as a definite clinical entity.

One interesting case of aneurysm involved the left sinus of Valsalva. There was an aortic regurgitation. The film revealed a prominent pulmonic knob due to displacement of the pulmonary artery by the aneurysm (Fig 24). The diagnosis was confirmed at autopsy. In such cases there is usually an aortic

Fig 16.

Fig 18—Large calcified aneurysm of the descending arch of the aorta. Note the widened and calcified descending thoracic aorta just below the large sac.

Fig 19—Aneurysm of the innominate artery, associated with early luetic aortic regurgitation and slight cardiac enlargement. The diagnosis was made from the physical findings. There was a pulsating mass in the right supraclavicular fossa, a tracheal tug and marked dyspnea.

regurgitation The pulmonary artery, interventricular septum, right or left atrium may be displaced or compressed

Another case of aneurysm of the abdominal aorta led to a very marked hypertension The aneurysm, in a colored man aged twenty-one, was produced by a gumma of the media The hypertension was most likely due to partial occlusion of one renal artery by the aneurysm

SYMPTOMS OF ANEURYSM

The most common symptom of aneurysm is *pain* This is usually due to erosion of bony structures, or pressure on nerve trunks (Figs 17, 21, 25) When a stenosis of the coronary ostia develops, angina pectoris also occurs I have often emphasized in clinics that there are two important causes of persistent thoracic

Fig 20

Fig 21

Fig 20—Large saccular aneurysm of the descending thoracic aorta with backache and dysphagia Note the dilated aorta below the sac, visible through the heart shadow There was no aortic regurgitation, hence no cardiac enlargement

Fig 21—Same patient as Figure 20, lateral view Note the large aneurysmal sac, and the definite erosion of the seventh and eighth thoracic vertebrae.

pain in adults, namely pulmonary neoplasm and aneurysm In many cases the diagnosis of aneurysm is made by mere inspection of the anterior and posterior chest wall There may be a visible pulsation in the painful area in the sternal, parasternal, or left paravertebral regions This plus a tracheal tug or difference

in the radial pulses, or an aortic regurgitation, makes the diagnosis very easy. Yet the roentgenographic findings based only on a film may be very confusing, especially with atelectasis of an entire lung or a hemorrhagic pleuritis, or unsharp outline of the aneurysm due to infiltration of adjacent structures with blood (Figs 22, 26)

Dyspnea due to tracheal or bronchial compression is the next most common symptom. Not only is the trachea or bronchus displaced or compressed, but the cartilages may be destroyed with collapse and death from asphyxia. Often the patient assumes

Fig 22

Fig 23

Fig 22—Large aneurysm of the entire arch of the aorta with left hemothorax. Aspiration yielded bloody fluid. A diagnosis of slow bleeding into the pleura was made clinically and confirmed (autopsy)

Fig 23—Large saccular aneurysm of the ascending aorta, with diffuse dilation and some atheromatosis of the arch and descending thoracic aorta. There was no aortic regurgitation, hence the heart was not enlarged

an odd position in which he gets some relief. Recently I had a patient with an aneurysm of the arch who was more comfortable on his stomach in an opisthotonos position, which he occupied most of the time. Others lie on the left side, or assume a knee-chest position.

Cough is the third most frequent symptom, often accompanied by hoarseness. The cough is persistent, leading to marked cyanosis. I have found *dysphagia* much more common than textbooks and articles on aortitis indicate. *Hoarseness* due to involvement of the left recurrent laryngeal nerve often occurs with large aneurysms of the aortic arch.

Fig 26

Fig 26—Large aneurysm of the aortic arch with compression of the left bronchus, atelectasis of the left lung, and left hemothorax.

Fig 27—Findings after aspiration of the left chest. Note the large aneurysm of the arch and the atelectatic left lung

A roentgenographic study consisting of careful fluoroscopy and films in various positions is of the greatest value. The pres-

ence of dilatation of other parts of the aorta may be decisive in a differential diagnosis (Fig 20)

Aneurysm of the innominate artery may be diagnosed by finding the throbbing in the right supraclavicular fossa, a palpable pulsating mass, a thrill, often a diminished right radial pulse, pressure upon the trachea, and a tracheal tug (Fig 19)

Aneurysm of the abdominal aorta will be diagnosed more frequently if the abdomen is carefully palpated in all luetics, especially those with thoracic aneurysm. Although some may be arteriosclerotic, the majority of abdominal aneurysms are due to syphilis. Abdominal pain, a pulsating expansile mass, and roentgenographic evidence when accompanied by atheromatosis make the diagnosis easy in most cases. The aneurysm may lead to hypertension by causing renal ischemia, may erode the spine, compress or split the diaphragm, lead to embolism of the mesenteric artery, or may rupture.

DIAGNOSIS OF SYPHILITIC AORTITIS

In luetic aortitis the diagnosis is of greatest value to the patient in the early uncomplicated stage, before aortic regurgitation, aneurysm, or angina pectoris has developed. I shall, therefore, stress the signs which I have found most useful in the diagnosis of uncomplicated aortitis.

In the first few years after the primary infection a clinical diagnosis of syphilitic aortitis is usually not possible, although histologic changes may already be present.

The earliest and most important diagnostic sign is a *widening of the ascending aorta, or any other part of the aorta, on fluoroscopic examination*. An examination of hundreds of normal as well as syphilitic aortas will give the observer a good idea of the normal size of the aorta in persons of various size and weight.

The entire contour of the ascending, arch, and part of the descending aorta can be very quickly observed by the trained examiner. Unfortunately we are unable to visualize the first inch or more of the aorta, including the aortic ring, where syphilis does its greatest harm.

A convex prominence of the ascending aorta, often with increased pulsation in this area, is quite characteristic (Fig 12). An ascending aorta more than 3 to 4 cm in diameter in an adult should be suspected of being luetic. This is especially true when the patient has a positive serologic test, Argyll-Robertson pupils

absent patellar reflexes, tabes or paresis. Unfortunately, only about 75 per cent of patients with cardiovascular syphilis have a positive Wassermann or Kahn test, a negative test thus occurring in about one fourth of the cases.

In the right oblique position the ascending aorta can be measured quite accurately. Its increased diameter, convex prominence to the right, and increased density proportional to its dilatation make the diagnosis. The aortic knob on the left is often enlarged and extends farther upward and to the left. Giving barium paste enables one to measure the descending portion of the arch, from the concavity in the esophagus wall to the left border (Kreuzfuch's method). The normal symmetry is often disturbed, and the arch becomes asymmetrical. It must be remembered that aortitis and atherosclerosis are frequently combined. It is never safe to assume a marked dilatation as due to atheromatosis or hypertension. A definite aneurysm of the ascending aorta or arch is practically always luetic.

The patient should be rotated in the left as well as right oblique position. Any departure from the cylindrical form is significant.

The second most important sign in aortitis without regurgitation is the *increased and widened manubrial dulness on percussion, especially to the right*. There may be a slight pulsation in the second or third right interspace on deep exhalation, or the second or third left interspace.

The third most frequent finding is the *tambour or bell-like, ringing, aortic second sound* first described by Potain. This peculiar musical quality may be due to the increased tension on the aortic cusps produced by stretching of the ring. The heart sounds are often unusually well transmitted because of the thinning of the lung by the expanding aorta. The aorta lies in contact with the chest wall. The tambour second sound is heard in a small area, usually to the right of the sternum. To the trained ear the tambour second sound is diagnostic of uncomplicated syphilitic aortitis. It may be present before there is any demonstrable widening of the aorta, thus being the earliest sign of aortitis.

A fourth frequent finding is a *systolic murmur at the base*, found in about two thirds of the cases of uncomplicated aortitis, and in practically all the cases of aortic regurgitation accompanying the diastolic murmur. The murmur is often harsh and

heard best in the second right or left intercostal space near the sternum. It must be remembered that a systolic murmur at the base is a frequent finding in patients past middle life, due to atheromatosis or sclerosis of the cusps in the absence of aortic syphilis. Therefore, a systolic murmur alone is not diagnostic of aortitis. I believe that the systolic murmur in syphilitic aortitis is more likely due to the stretching of the aortic ring with increased tension upon the cusps in systole. This prevents them from approximating the wall of the aorta. The projection of the cusps under tension produces the systolic murmur. It persists after separation of the cusps, hence the double murmur of aortic regurgitation.

A fifth sign in the diagnosis of syphilitic aortitis is the *pulsus differens*, or even total absence of pulsation in one or more of the main branches of the aorta (innominate, left carotid, left subclavian). When the left carotid and subclavian pulse, or only the subclavian, is weaker than the right an isthmus stenosis must be considered. This is usually not difficult to diagnose, especially when the blood pressure in the lower extremity is low and the ribs reveal the characteristic erosions.

Inequality of the radial pulses is common in aortitis. All three ostia of the main arteries may be involved, as in one of my cases. There was no pulsation in either arm or the right carotid. There was a systolic murmur and thrill over the left carotid. Our diagnosis was a luetic aortitis with occlusion of the ostium of the innominate and left subclavian arteries, and stenosis of the ostium of the left carotid. This was confirmed at autopsy. There was also an anomalous vertebral artery coming from the aortic arch.

A sixth sign of syphilitic aortitis is the *presence of an aneurysm of any part of the thoracic aorta*. We have seen a number of aneurysms of the innominate artery.

Angina pectoris is quite frequent in luetic aortitis. It is usually of a severe type and progressive. The pain is due to the stenosis or occlusion of the coronary ostia. Another factor is the lowering of the diastolic blood pressure when aortic regurgitation develops. A certain number of the patients have hypertension with cardiac hypertrophy. The increase in the volume of the heart muscle causes a still greater demand for oxygen at the same time that the blood supply is being slowly reduced.

Another sign of value is the presence of a *suprasternal pulsa-*

tion, due to dilatation and elongation of the aortic arch. At times the dilated aortic arch may be palpable in the episternal region.

DIAGNOSIS OF AORTIC REGURGITATION

Aortic regurgitation, the only valvular disease caused by syphilis, except for the rare pulmonary regurgitation, is seen most often in the fifth and sixth decades. Occasionally we find it before the age of thirty-five years. The diagnosis of aortic insufficiency is usually an easy matter.

First and most characteristic is *the diastolic murmur at the base*. In the early stage it may be missed unless one listens carefully during forced exhalation with the patient leaning forward. It may be heard in the aortic area, in the second or third right or left interspace near the sternum. As the disease progresses and the aorta dilates, the latter lies close to the chest wall to the right of the sternum, hence the murmur in advanced cases is often loudest in the second and third right interspaces. There is usually an accompanying *systolic murmur*, which I believe is best explained as due to tension on the cusps so that they cannot approximate the aortic wall during the systole.

Later there is a disappearance of the aortic second sound and only the two murmurs are heard. The pulse pressure increases, and the heart enlarges especially to the left. In the majority of cases the lesion can be suspected from the *elevated systolic and lowered diastolic pressures*. There are few other causes of increased pulse pressure, namely, thyrotoxicosis, senile arteriosclerosis, and total heart block.

Frequently the diagnosis can be made at a distance by noting the hopping carotid arteries with synchronous vibration of the head. The *Corrigan pulse* and *Duroziez sign* on compression of the femoral or other large artery are quite characteristic. A capillary pulse is often present, but not diagnostic as we see it in other conditions.

In the past twenty years I have seen three cases of luetic aortic regurgitation with an unusually loud musical diastolic murmur associated with a diastolic thrill. The thrill was most marked in the second or third right intercostal space. I have offered as one explanation for this unusual murmur and thrill the presence of a fenestrum of one or more of the aortic cusps.

Differential Diagnosis between Luetic and Rheumatic Regurgitation

The differential diagnosis between luetic and rheumatic aortic regurgitation may be difficult in exceptional cases. The presence of an associated organic mitral lesion speaks for rheumatic endocarditis. The same is true when an aortic stenosis is present. An aortic regurgitation, therefore, in the absence of any other organic valvular disease in an adult, is most likely luetic. The presence of aortic dilatation or aneurysm makes the diagnosis quite certain, even in the 25 per cent with a negative Wassermann or Kahn test.

I have seen three cases of combined rheumatic and luetic disease in which the diagnosis of both types of lesion was possible. In two there was a definite stenosis of the aortic ostium, which is never luetic, associated with an aortic aneurysm. In one there was an old rheumatic mitral stenosis and regurgitation, a history of chancre twenty-five years ago, and a luetic aortic regurgitation with an aneurysm of the ascending aorta. In rare cases a bacterial endocarditis may be engrafted on a syphilitic aortic valve.

In the absence of a widening of the aorta, of a positive serologic test or other evidence of syphilis, or of other valvular disease, it would be impossible to say whether the lesion is luetic or rheumatic. To state that syphilitic and rheumatic or syphilitic and subacute bacterial disease do not occasionally occur in the same patient is incorrect. I have seen such combinations several times both clinically and at necropsy.

CONCLUSION

In conclusion, I wish to emphasize the importance of a periodic careful physical examination and roentgenographic study, for the presence of luetic aortitis, of every patient with evidence of syphilis. The diagnosis of uncomplicated aortitis is possible in a considerable percentage of all cases.

The most valuable aids are (1) careful fluoroscopic examination, (2) tambour aortic second sound, (3) increased manubrial dulness especially in the second and third intercostal space, (4) visible pulsation in the second or third intercostal spaces or suprasternal, (5) difference in the radial or carotid pulses, (6) angina pectoris in a young adult in the absence of other cause. An early diagnosis followed by intensive antiluetic therapy will prevent most cases of aortic regurgitation and aneurysm.

SUBACUTE BACTERIAL ENDOCARDITIS

and

DONALD A. HIRSCH, M.D.§

PRESENTATION OF A CASE

TODAY, I shall present a patient and discuss in detail a problem of relatively rare occurrence which has assumed considerable importance, however, because of a new approach in the matter of therapy

The Patient's History—Our patient, Miss J. T., is twenty-four years old and obviously is acutely ill. Her bedside history reveals the following: At the age of eleven, she had acute inflammatory rheumatism (acute rheumatic fever). The disease ran a typical course—involvement of the larger joints, knees, ankles and elbows, with pyrexia and an early invasion of the heart. Five years later, when she was sixteen years of age, she developed chorea with an acute exacerbation of the heart symptoms and was kept at bed rest for four months. She made a temporary and relative recovery and was able to be up and around and go to school.

She was restricted in her activities, however, and was told that she had "a leaky mitral valve." This was both an interesting and fairly accurate diagnosis, because while acute rheumatic fever, as we all know, is responsible for the vast bulk of acute cardiac valvular disease in youth, it may and does affect both the mitral and the aortic valves. Chorea, on the other hand, has a more specific and selective action and with few exceptions involves the mitral cusps exclusively. Accordingly, the diagnosis of "mitral heart dis-

† Clinical Professor of Medicine, Loyola University School of Medicine, Director of Heart Station, Mercy Hospital—Loyola University Clinics

‡ Clinical Associate in Medicine, Loyola University School of Medicine, Associate Director of Heart Station, Mercy Hospital—Loyola University Clinics (Now Major, Medical Corps, Army of the United States)

§ Clinical Instructor in Medicine, Loyola University School of Medicine, Assistant Director of Heart Station, Mercy Hospital—Loyola University Clinics (Now Captain, Medical Corps, Army of the United States)

case" following both an acute rheumatic infection and five years later a typical chorea, renders the diagnosis of mitral heart disease from the history alone both interesting and logical

For the next seven years, from the age of sixteen to twenty-three, this young lady was relatively free from heart symptoms and was able to carry on a gainful occupation (clerk in a law office) Two months ago she developed a mild sore throat followed by a severe chill and elevated temperature, heart consciousness and dyspnea While her symptoms have subsided, she has been confined to bed An important negative point in her recent history, which I wish to emphasize before passing on to the physical examination, is that she has had no recurrence of her rheumatism or of her chorea—and *that* in spite of marked exacerbation of the heart symptoms

Physical Findings—We are dealing with a young woman who is acutely ill Her color is pallid (a secondary anemia), the lips are cyanosed, and she is dyspneic The temperature is 102° F, the pulse rate is 130, and the respiratory rate while the patient is lying in bed is 30

The heart reveals the following Percussion measurements certified by telefluoroscopy, are right ventricle 6 cm transverse 14 cm. The left auriculoventricular sulcus is "convex" A murmur, pre-systolic in time, is easily audible over the apex and is confined to the fifth and sixth left interspaces In a word, the patient has a well developed and, from extracardiac signs, a decompensated mitral stenosis due to rheumatism and chorea

The lungs and pleura are normal but the liver is definitely enlarged and pulsating More interesting, however is the left hypochondrium where a mass is easily palpable, apparently the spleen The skin over the abdomen reveals a few discrete, pinkish petechiae.

Laboratory Findings—Urine shows albumin, pus, casts and red blood cells, blood, a mild secondary anemia with a marked leukocytosis (23,000) Blood culture reveals a nonhemolytic streptococcus with no other organisms

Diagnosis—The "actual" diagnosis in this particular instance is simple and certified because of a combination of pre-existing rheumatic and choreic mitral stenosis, a seven-year interval free from cardiac symptoms and from apparent reinfections, and then a sudden acute episode ushered in with sore throat, chill and pyrexia with "entire absence of joint pains or choreic manifestations" Finally, the enlarged spleen, petechiae, and blood culture of non-hemolytic streptococci render the diagnosis of subacute bacterial endocarditis complete

With the diagnosis definitely certified in this particular patient, let us now review (in the absence of the patient) the

general subject of subacute bacterial endocarditis, particularly as regards the prognosis and treatment

ETIOLOGY

The direct cause of subacute bacterial endocarditis is always the *Streptococcus viridans*. Interestingly, however, this organism never attacks a previously normal heart valve. Subacute bacterial endocarditis is always seen in a valve previously diseased or malformed. Accordingly we encounter the history and physical findings of either a congenital heart lesion or an old quiescent rheumatic heart in all instances. The congenital heart lesions, however, which almost always are found in the right heart as in pulmonary stenosis, patent ductus arteriosus and patency of the interventricular septum, are relatively infrequent as a predisposing factor (less than 5 per cent), the disease usually being implanted on old rheumatic hearts. Here, too, there is some selectivity. The mitral and aortic valves alone or together provide most of the sites for its occurrence. A further interesting point is that a well defined so-called "buttonhole type" of mitral stenosis associated with auricular fibrillation and acute decompensation is rarely complicated by subacute bacterial endocarditis.

In brief, subacute bacterial endocarditis is most frequently encountered in mitral and aortic insufficiencies due to a previous rheumatic endocarditis, and in compensated mitral stenosis with a normal cardiac rhythm. Only infrequently does this disease develop in patients with auricular fibrillation or with symptoms or signs of congestive heart failure.

PATHOLOGICAL SITE—VALVES INVOLVED

As previously stated, subacute bacterial endocarditis is practically never a primary lesion but one superimposed either on an old congenital valve deformity (which type constitutes possibly 5 per cent or even less of all cases) or upon a previous rheumatic endocarditis. It is interesting to note how percentages of valve involvement differ in the literature. In our experience, mitral lesions predominate over aortic in great preponderance. This seems to us logical, too, for clinical reasons. In the first place, rheumatic endocarditis is more frequently associated with the mitral valve than with the aortic valve. We encounter mitral insufficiency and mitral stenosis, one or the other, or the two

combined, at least three times as frequently as we do an uncomplicated aortic insufficiency, which of itself accounts for the common combination of mitral rheumatic heart disease and subacute bacterial endocarditis.

In the second place, chorea practically limits itself to the mitral valve. We have in our records of more than one hundred cases of endocarditis due to chorea no instance of uncomplicated aortic disease. From our experience, therefore, we feel convinced that in rheumatic and choreic hearts the mitral valve is the valve of choice and frequency in a later subacute bacterial endocardial invasion.

DIAGNOSIS

The correct interpretation of disease in an individual who is not only acutely ill but has definite heart symptoms and signs is not so simple as might be anticipated. As a rule, the patient with subacute bacterial endocarditis gives the history of a previous rheumatic endocarditis. After a varying period he has suffered a sore throat or developed a local focus of infection such as an infected tooth, a head cold, or a mild influenza. In a word, an individual, usually youthful, with a history of a previous rheumatic endocarditis, not totally incapacitated, often ambulatory and at work or in school, as a result of a secondary infection suddenly becomes acutely ill with a rapid and progressive exacerbation of cardiac symptoms and signs. Loss of appetite, sweats and alternating mild chills develop and persist in spite of treatment. There is a progressive loss of weight and strength. Elevation of temperature is an early and constant symptom, ranging from a moderate degree of 100° to 101°F , to 103°F and even higher as the infection progresses.

As a rule, within two weeks from the advent of a persistent fever, distinguishing *physical signs* appear, which accumulatively have considerable diagnostic significance.

1 *Petechiae*, or hemorrhagic spots, minute, 2 to 3 mm in diameter, appear both on mucous surfaces and on the skin, most commonly on the conjunctivae, the lips, or the skin of the abdomen and chest. They of themselves, if they occur in numbers and persist, speak for a bacterial endocarditis, particularly in the presence of clinical evidence of an endocarditis.

2 An *enlarged palpable spleen* associated with a definite heart murmur in a youthful individual who is obviously acutely and critically ill and who shows no signs of acute cardiac decompensation.

sation such as an enlarged liver or extremity edema, is almost diagnostic

3 *Hematuria*, or more particularly the presence of a very considerable number of red blood cells microscopically in the urine of a youthful cardiopath, in the absence of evidence of a primarily diseased kidney, is very significant

4 My associates and I must take exception to the importance placed in medical literature upon the symptom or sign of *clubbing of the fingers* in subacute bacterial endocarditis. In the first place, in our experience we do not encounter "clubbed fingers" frequently enough in this disease to consider it an important diagnostic sign. Furthermore, we find this "clubbing" and "painful finger tips" in congenital forms of heart disease, in cor pulmonalis, and even in acute bacterial endocarditis, so we have come to consider it a sign of minor diagnostic importance

5 Systemic spread through the agency of *emboli* is of very considerable diagnostic importance. Emboli are very common in the spleen and explain the acute sharp pain complained of in the left hypochondrium and occasionally referred up into the left lower thorax. Less frequently they occur in the kidney and still more seldom in the brain. Occasionally, too, small emboli become dislodged and result in pulmonary infarction. It is important to remember the potential embolic possibilities in subacute bacterial endocarditis

6 *Positive blood culture* of *Streptococcus viridans* (green-producing) is of course diagnostic, because it is rarely isolated in any other form of acute endocarditis. On the other hand, a negative culture is inconclusive, for in an impressive percentage of clinically proven instances of subacute bacterial endocarditis the *Streptococcus viridans* is never isolated

Differential Diagnosis

The differential diagnosis between subacute bacterial endocarditis and *an acute exacerbation or recurrence of rheumatic endocarditis* can be very confusing for the following reasons: (1) In both conditions a history of a previous rheumatic infection is given. (2) Both show similar physical signs. (3) Both not infrequently run a similar course, with elevation of temperature, acceleration of pulse and exaggeration of heart symptoms and signs.

The following points, however, are helpful in the differential diagnosis

1 A person with subacute bacterial endocarditis is almost always more acutely ill than one with recurrent rheumatic endocarditis, with a higher temperature range, more profuse sweating, and so forth

2 In subacute bacterial endocarditis there is usually no history of recent joint pains or, in the case of a choreic heart, of a return of the choreic symptoms, the heart symptoms and signs alone are in the picture

3 While a leukocytosis is the rule both in subacute bacterial endocarditis and in recurrent rheumatic endocarditis, it is usually decidedly more pronounced in the former

4 Hematuria is the "rule" in subacute bacterial endocarditis and the "exception" in the recurrent rheumatic

5 Finally, petechiae and an enlarged palpable spleen are practically pathognomonic of subacute bacterial endocarditis, and, if obtained, a blood culture of *Streptococcus viridans* certifies the diagnosis.

Occasionally subacute bacterial endocarditis is differentiated with difficulty from *acute bacterial endocarditis* for the following reasons (1) In both conditions the individual is acutely and critically ill, with very definite cardiac symptoms and signs (2) The patient for diverse reasons may be unable to provide the history of a previous rheumatic or choreic infection (3) The disease directly responsible for the acute bacterial endocarditis may be obscure or the organism difficult to isolate

Ordinarily, however, acute bacterial endocarditis can be fairly readily differentiated from the subacute type on the following points

1 The patient with acute bacterial endocarditis not only has heart symptoms and signs but has them as a complication of a severe constitutional disease present at the moment This disease may be a concurrent pneumonia, a tuberculosis, a gonorrheal infection, or any disease due to the pyogenic organisms

2 The patient as a rule is more desperately and acutely ill

3 There is no history and there are no signs of a previous rheumatic heart

4 Petechiae are uncommon

5 The blood culture for *Streptococcus viridans* is negative,

and we may be able to isolate the organism responsible for the acute infection

PROGNOSIS

I approach this subject with considerable caution and pessimism. It is true that a combination of new therapeutic measures offered within the past few years has, in the medical literature at least, altered the picture so far as the mediate and immediate outlook of these patients is concerned. Possibly the outlook is a bit brighter, particularly as regards the immediate prognosis. Maybe the disease in some of these persons becomes arrested, quiescent, and reinfection is avoided for a considerable time. This is particularly true if, as some writers and clinicians insist, the newer methods of treatment are used not only vigorously but prophylactically as well. However, subacute bacterial endocarditis once fully developed and certified is a fatal disease—not as rapidly fatal as the acute type of bacterial endocarditis, but complete recovery in the experience of my associates and myself is rare indeed.

TREATMENT

The management of subacute bacterial endocarditis is a controversial subject. As in the case of the prognosis, I feel uncertain and pessimistic regarding the treatment of this type of heart disease. However, in apology I ought to state that in our clinic we encounter subacute bacterial endocarditis not early, not in a preclinical or a prophylactic stage, but, as a rule, only after the disease is well developed. This may in a measure explain why in our own limited experience our results are unsatisfactory.

Our routine treatment of subacute bacterial endocarditis is as follows:

1. Absolute bed rest, with no temporizing because of orthopnea, heart consciousness or any other symptom or group of symptoms which might suggest the advisability of semi-invalidism.
2. Diet, soft and bland, with fluids to 2000 cc daily, orally preferred, and if not practical, intravenously.
3. Fever therapy in the absence of contraindications, but as a rule we prefer radiation heat to the parenteral type (intravenous typhoid, etc.).
4. We use the sulfonamides routinely, the types and dosages determined individually.
5. A combination of the sulfonamides and heparin frequently has a favorable clinical reaction.

6 General and symptomatic management is important and should include the following (a) Ice bag to the precordium in the presence of a rapid and forceful heart. (b) Sedatives during the day, particularly the barbiturates, and narcotics short of the opium compounds for sleep at night (c) Blood transfusions are helpful and indicated if the total red cell count drops rapidly and progressively under three million In this connection, too, liver therapy orally and intramuscularly has a marked temporary value (d) I have used thiamine chloride intravenously with startling temporary results

CONCLUSIONS

My associates and I have this morning demonstrated a patient a young woman, with a typical and certified (clinically and by blood culture) subacute bacterial endocarditis We have made the following observations concerning subacute bacterial endocarditis in general

1 It is not a "primary" disease, but both clinically and pathologically it is an implantation upon a heart valve previously malformed (congenital) or diseased (due to rheumatism or chorea)

2 We have reviewed the average clinical course of this disease, both as to symptoms and to signs.

3 We have discussed the diagnosis and differential diagnosis, pointing out the complexities and confusions, particularly between subacute bacterial endocarditis and a recurrent acute rheumatic endocarditis and, less frequently, an atypical acute bacterial endocarditis

4 We stress the fact that, compared with the great number of youthful individuals suffering with acute rheumatic endocarditis, subacute bacterial endocarditis is relatively uncommon, and we do not agree that anywhere near 20 per cent of these patients develop subacute bacterial endocarditis as a terminal complication

5 Finally, I have attempted to give an unbiased opinion concerning both the prognosis and treatment, including the newer methods of chemotherapy and the sulfonamides In our experience, subacute bacterial endocarditis, proved clinically and certified by blood culture (*Streptococcus viridans*), is nearly always a fatal disease We feel that a combination of sulfonamide therapy, thiamine chloride intravenously and blood trans-

fusions definitely improve the clinical picture temporarily, but we are unconvinced that these measures pushed heroically are ever completely effective in curing it.

COMMON FORMS OF CONGENITAL HEART DISEASE*

WRIGHT ADAMS, MD† and DONALD E. CASSELS MD‡

THE complexity and variety of congenital heart lesions make accurate anatomic diagnosis difficult and in some cases impossible before death. The progress that has been made has come chiefly from the correlation of clinical with autopsy findings. Studies of this kind have been difficult for the clinician primarily because the relative infrequency of the disease and the great variety of the lesions have prevented the accumulation of adequate series of patients in which the diagnosis has been confirmed by autopsy after careful clinical study. More work of this kind is necessary but enough information is available to make possible an anatomical diagnosis before death in most instances.

Often an incomplete diagnosis is of considerable value and in most cases an incomplete anatomical diagnosis together with a careful functional evaluation of the patient will make possible more accurate prognosis and intelligent treatment than will an accurate anatomical diagnosis alone.

Interventricular septal defect may be mentioned as an example of the value of an incomplete anatomical diagnosis. If cyanosis occurs in conjunction with findings of such a lesion it is often impossible to determine whether cyanosis occurs because of the large size of the defect or because it is accompanied by some other lesion such as transposition of the aorta. While the diagnosis must remain incomplete, this need not cause confusion in the prognosis. There is every reason to believe that the degree of the cyanosis, the size of the heart and the severity of symptoms will determine the prognosis and guide the management of the patient under these circumstances in the absence of exact

* From the Departments of Medicine and Pediatrics, University of Chicago. This work was supported in part by the Kenneth G. Smith Foundation.

† Associate Professor of Medicine, University of Chicago School of Medicine.

‡ Assistant Professor of Pediatrics, University of Chicago School of Medicine (Now Captain, Medical Corps, Army of the United States.)

knowledge regarding the minutiae of the lesion. The incidence of subacute bacterial endocarditis is about the same for both types of lesion. Exact identification of the lesion would not facilitate management of the patient in this case.

DIAGNOSIS

The diagnostic outline published in the "Criteria for Classification and Diagnosis of Heart Disease,"¹ which involves the description of each case according to etiology, anatomical lesions, physiological abnormalities and functional capacity, is as useful in cases of congenital heart disease as in other types. The more complete the diagnosis, the more valuable it will be.

ETIOLOGICAL DIAGNOSIS

During infancy the frequency of congenital lesions is so great as compared to acquired heart disease that except under unusual circumstances it is justifiable to assume that any organic disease is congenital. It follows that in the adult a definite history of abnormality extending back to infancy increases the probability that an organic lesion is congenital.

In many instances recognition of a specific lesion is the first step in diagnosis and its congenital etiology is clear because of its type.

Occasionally the diagnosis of congenital heart disease is made through exclusion, a group of atypical findings being judged to represent a congenital defect because of the lack of resemblance to any common acquired condition. This method can usually be avoided by careful study and is no more accurate than are other kinds of diagnosis by exclusion.

The differentiation of functional heart murmurs from those of congenital heart disease is frequently difficult, the problem being similar to that encountered in distinguishing between other organic disease and functional murmurs in adults but not in children. The most frequent murmur in congenital heart disease is a systolic murmur at the left of the sternum. This is also a common location for functional murmurs. The presence of a thrill, a diastolic murmur, enlargement of the heart, cyanosis, electrocardiographic abnormality or other evidence of organic heart disease gives positive indication of organic disease. The absence of such findings, however, does not indicate that a murmur is functional. The loudness of the murmur is of some help

but cannot be relied upon to differentiate the two types. The younger the patient the greater the difficulty. Functional murmurs are often relatively loud in infancy and the typical murmurs of specific congenital lesions are often late in developing so that great caution in drawing definite conclusions from equivocal findings is necessary. In infancy, for practical purposes, all murmurs are functional or indicate congenital heart disease but in spite of this differentiation is often impossible.

ANATOMICAL DIAGNOSIS

Thorough and extensive pathological study forms the only sound basis for anatomical diagnosis. Abbott's² classification of 1000 cases is a classical contribution in this field and is invaluable as a reference source. The relative frequency of different types of congenital lesions varies considerably in other series, however, and this series must not be given too much weight because of its size in estimating frequency. The group is derived from many sources, including some individually reported cases, and may not represent a random sample of congenital heart lesions. The series of Gibson and Clifton,³ composed of 105 autopsied cases from one hospital, is in sharp contrast to the Abbott series in some respects. For example, 34 per cent of the latter group had permanent cyanosis but only 2 per cent of the former showed this complication. This is a much greater disparity than would be expected on the basis of chance. While caution is necessary in drawing conclusions from autopsy series regarding the frequency of occurrence of various lesions in clinical practice, they are of course indispensable in establishing the significance of physical signs.

Classification

The great number of congenital lesions (there are eighty-seven included in the Abbott table), together with the fact that there is a strong tendency for lesions to occur in combination, has made it difficult to group patients from a clinical standpoint. The classifications of White⁴ and Dry⁵ and Brown⁶ are notable efforts in simplifying complex pathological knowledge to make it useful clinically. However, any classification which includes all types of congenital lesions, whether anatomical, embryological or clinical, must be complicated.

A classification according to the obvious clinical sign which

attracts attention to the fact that an abnormality of the heart exists is definitely inferior to others in the systematic study of congenital heart disease from a scientific point of view but it is justified because it systematizes the clinical approach to the diagnostic problem. In classifying patients during diagnosis it is helpful for the physician to emphasize findings that are demonstrable in the living patient rather than anatomical lesions or embryological origins of lesions, even though his aim is to make a diagnosis that is as accurate as possible anatomically. The classification given below simplifies the reasoning involved in diagnosis and frequently makes possible greater accuracy in the final diagnosis than efforts to fit clinical observation to an anatomical classification directly.

CLASSIFICATION OF PATIENTS WITH CONGENITAL HEART DISEASE ACCORDING TO COMMON PHYSICAL SIGNS

- 1 Patients with a systolic murmur heard at the left sternal border
- 2 Patients with cyanosis
- 3 Patients with the continuous murmur of patent ductus arteriosus
- 4 Patients with arterial hypertension
- 5 Other patients with congenital heart disease

To make such a classification complete the final miscellaneous group is necessary. The great majority of clinically important cases fall in the first four groups, however, and the simplicity and utility of the classification from a practical standpoint justify this short form, although it is recognized that many subdivisions of group five exist.

1 Patients with a Systolic Murmur Heard at the Left Sternal Border

This group includes nearly half of clinically recognizable congenital heart disease. It can, to some extent, be subdivided on the basis of the location of the murmur. The murmur of *patent interventricular septal defect* is best heard in the third left interspace in most cases, while *pulmonary stenosis* is characterized by a murmur in the second left interspace, and the murmur of *patent ductus arteriosus* is best heard in the first interspace in most cases. *Transposition of the great vessels* is a common complicating defect but does not alter the location of the murmur. Differentiation on the basis of localization of the murmur is uncertain, however, deviation from characteristic locations being

common In infancy and childhood these murmurs tend to be localized at a lower level and are often heard as far down as the fourth or fifth interspace

All of these murmurs are frequently accompanied by thrills, so that the presence of a thrill does not help in differentiation between these lesions, but its location does The characteristic localization of the thrill in these lesions is the same as that of the murmurs The point of maximum intensity of the thrill is somewhat more reliable diagnostically than the point where the murmur is loudest The presence of a thrill helps to distinguish the murmurs of this group of congenital lesions from functional and other rare congenital murmurs The direction of transmission is characteristic, the murmurs of pulmonary stenosis and patent ductus arteriosus being transmitted toward the left shoulder, the murmur of transposition of the aorta to the neck and the murmur of interventricular septal defect toward the apex

Under the heading of etiological diagnosis the difficulty in differentiating systolic murmurs of congenital and functional origin has been stressed This difficulty is frequently encountered in distinguishing specific lesions as well Murmurs and thrills may appear and become prominent after a few weeks when the physical signs have been normal at birth and murmurs that have been easily heard soon after birth may disappear entirely It is not justifiable to make a diagnosis of a specific lesion from the finding of a systolic murmur without supporting evidence in the first weeks of life On the other hand, it is impossible to be sure that such a systolic murmur is functional in early infancy

Any of the lesions in this group cause enlargement of the right ventricle apparent on physical or roentgenologic examination Enlargement of the right ventricle without enlargement of the pulmonary conus suggests pulmonary stenosis All of this group of lesions may cause right axis deviation of the electrocardiogram Defects of intraventricular conduction suggest a septal defect but normal QRS complexes are not evidence of an intact septum In general the roentgenogram and electrocardiogram are more helpful in judging the severity of lesions in this group and in separating these from other lesions than in distinguishing between them The absence of right ventricular enlargement in the roentgenogram and right axis deviation in the electrocardiogram does not indicate that a systolic murmur

is functional rather than of congenital origin but it does usually indicate that the lesion is not of great severity. Fluoroscopic examination with rotation of the patient during examination is much more valuable than is the standard chest film.

These laboratory examinations are less valuable in infants and small children than in adults. Satisfactory roentgenograms are more difficult to obtain because of poor cooperation. Even in satisfactory films the wide mediastinum and rounded globular heart of infancy show little resemblance to the cardiac silhouette in the adult. Abnormalities of chamber contour are hard to recognize and the shape often changes from one picture to another, the changes being related to respiration or crying. Angiocardiography will doubtless be of value in some cases, but is not at present completely established. This method has been the subject of a recent review by Sussman, Grishman and Steinberg.¹ The electrocardiogram in infancy is also more variable and of less value than in the adult.

In a considerable proportion of the patients in this group the detection of individual lesions is impossible. The confusion is made worse by the frequency with which lesions within the group occur in combination. Fortunately the inaccuracy that results from failure to distinguish between a patent interventricular septum and the same lesion in combination with partial transposition of the aorta, for example, is of very little practical significance. A large septal defect reduces cardiac reserve more than less severe combined lesions. The total reduction of efficiency is more important than the cause of the reduction. The incidence of subacute bacterial endocarditis is about the same in all lesions of this group. The susceptibility of the patients to other infections is dependent on the degree and direction of the shunt rather than upon its cause. When this group of lesions is differentiated from other conditions causing a systolic murmur in this location, the gain is small from more precise anatomical diagnosis.

2 Patients with Cyanosis

There is considerable overlapping between this and the preceding group and often the diagnosis of a specific lesion can be made in a cyanotic patient by the same methods indicated for Group 1. Most of the lesions with cyanosis are characterized by

a *shunt* which allows the passage of blood from the right to the left side of the heart. This may occur from defects in the auricular or ventricular septa or because of communications between the aorta and pulmonary arteries. Permanent cyanosis does not occur in these cases unless the shunt is large enough to permit mixing of the blood from the right and left sides of the heart. Normally the pressure on the left side of the heart is higher than on the right so that with small shunts the blood passes from left to right without causing cyanosis. In the presence of small shunts, however, right heart failure may reverse the pressure relationships and the direction of flow through the shunt and give rise to terminal or temporary cyanosis. Transposition of the great vessels may also give rise to cyanosis because some of the blood by-passes the pulmonary circulation. In a few instances cyanosis occurs in the absence of a shunt because of high-grade obstruction to the flow of blood, usually from pulmonary stenosis. These obstructive lesions may also occur with shunts.

A given lesion may occur in Group 1 or Group 2 or in both depending on its severity, for example, a small interventricular septal defect may cause a loud murmur but no cyanosis, if it is larger a murmur with cyanosis results, while in the case of very large defects, no murmur but pronounced cyanosis is common. This relationship between the murmur and cyanosis is not of great diagnostic help in this connection, however, because of the frequent combination of lesions. As might be expected, severe and complicated lesions are more frequent in the group with cyanosis than in the acyanotic group.

As might also be expected, permanent cyanosis is more common in the younger age groups. Since these lesions are in general more severe, the hazard is greater and many of this group die at an early age. Only a few deeply cyanotic children live to the age of twenty.

From the standpoint of anatomical diagnosis this group is important because it is composed almost entirely of cases with lesions causing large shunts and combined, complicated lesions. Exact anatomical diagnosis is frequently impossible in this group but recognition of the common significance of cyanosis makes possible intelligent management of the patient.

3 Patients with the Continuous Murmur of Patent Ductus Arteriosus

The classical murmur of patent ductus arteriosus is best heard in the first left interspace and it persists through all of systole and part or all of diastole. It is transmitted toward the left shoulder. If the patency is large, enlargement of the pulmonary artery is demonstrable by roentgenographic examination and peripheral signs resulting from the high pulse pressure are apparent. The peripheral signs are identical with those of aortic insufficiency, but the location and type of the murmur together with the enlargement of the pulmonary artery differentiate this lesion from aortic lesions.

It is very important that this lesion be recognized. It is relatively common, the open ductus is a frequent site of bacterial endocarditis and often causes heart failure, and it has been closed successfully by surgery in a number of instances.

Unfortunately, pathological studies have shown that patent ductus arteriosus may occur in the absence of the typical, easily recognized murmur. Some cases, especially in children, have caused only a systolic murmur and some have been found when no murmur at all has been noted. The other signs may help in detecting some of these cases but many will continue to be missed until new diagnostic methods are available.

4 Patients with Arterial Hypertension

Coarctation of the aorta, which is the congenital lesion which causes hypertension, can be recognized easily by the fact that the arterial pressure is higher in the arms than in the legs and by the fact that notching of the lower edges of the ribs is apparent on chest roentgenogram because of the enlargement of the intercostal arteries which are the principal collateral channels around the lesion. This roentgenographic sign is not as clear-cut in children as in adults. Failure to make the diagnosis of this lesion occurs because of failure to think of it as a possibility rather than from difficulty of diagnosis. Small degrees of coarctation which do not cause elevation of blood pressure in the upper extremities are not important clinically.

5 Other Patients with Congenital Heart Disease

This group will not be discussed at length because it is composed of lesions which are rare or in which diagnostic methods are unreliable or unsatisfactory. The great majority of clin-

ically important lesions are included in the first four groups. Defects of the interauricular septum, bicuspid valves, supernumerary valve leaflets, anomalous chordae and so forth give rise to no signs or to signs that are irregular and inconsistent and therefore an ante-mortem diagnosis is not made. A few lesions such as aortic stenosis and pulmonary insufficiency are rare but are rather easy to recognize. Some lesions such as anomalies of the aortic arch are usually found on roentgenographic examination. The clinical diagnosis of these uncommon lesions is sometimes possible, but they are encountered but rarely in practice and too much concentration on the rare clinical patterns is likely to do more harm than good because of the inevitable confusion that results.

PHYSIOLOGICAL DIAGNOSIS AND FUNCTIONAL EVALUATION

The one most important feature of physiological diagnosis that occurs in congenital heart disease alone is the estimation of the size and direction of shunts. Quantitative methods are not in general use. Generalities are unsafe, but usually the presence of cyanosis indicates a shunt of some magnitude from right to left. If a shunt is recognizable the degree of enlargement of the chamber receiving the blood gives some clue to its size.

The symptoms and signs of cardiac insufficiency, the arrhythmias and so forth have approximately the same significance as in acquired heart disease.

The methods used and the significance of functional evaluation are the same as in acquired heart disease. Physiological diagnosis and functional evaluation of the patient should be stressed in connection with congenital heart disease. They are frequently neglected because of the difficulty of anatomical diagnosis.

PROGNOSIS

The fact that patients with severe congenital heart lesions occasionally survive to great age does not indicate that prognosis is entirely impossible. Approximately the same degree of accuracy is possible as in other types of heart disease. The uncertainty that exists in regard to the development of subacute bacterial endocarditis is quite similar to the uncertainty regarding the recurrence of myocardial infarction. In each case the possibility of disaster can be foreseen but its likelihood is not sufficiently great to justify pessimism on the part of the patient.

As in severe rheumatic heart disease it is frequently possible to predict that the cardiac reserve will remain very low, but in neither case is it possible to predict the time of death with great accuracy. Too many unpredictable hazards are involved to estimate when any particular heart will become unable to support life.

In general in adults deterioration of cardiac functional capacity is slower in patients with congenital heart disease because the lesion itself is not progressive. The cardiac reserve can be estimated from the symptoms of heart failure which the patients experience. The prognosis for continuation of life may be improved if the patient's mode of life can be modified so that he avoids symptoms. Symptoms or signs of heart failure, cyanosis, and enlargement of the heart make for a bad prognosis. The intensity of these signs is important. Occasionally a person with deep cyanosis lives for many years, but he will be very unlikely to do so if his heart is big and he has heart failure. Occasionally a person with a very large heart lives for many years, but such a development is unlikely in the presence of cyanosis or heart failure. Throughout adult life the prognosis of congenital heart disease patients from the standpoint of cardiac function depends more upon these factors than upon the anatomical lesion.

Intercurrent infections have been a common cause of death in these patients. In general the susceptibility to such infections and their mortality rates are proportional to the reduction of functional capacity of the circulation. The large number of deaths from this cause may be somewhat reduced in the future as chemotherapy becomes more successful.

Subacute bacterial endocarditis is a serious hazard to some of these patients. Its frequency is high in cases with valve lesions and with interventricular shunts and arteriovenous shunts. It is very uncommon in interauricular septal defects. It is particularly frequent in patients with patent ductus arteriosus.

Prognosis is exceptionally difficult in early infancy. Many unpredictable deaths occur in the first year of life but on the other hand some patients with severe cyanosis at birth do surprisingly well. After the first year minor signs may disappear, but in general severely involved hearts do not improve. Those patients who have heart failure or marked enlargement of the heart in early childhood rarely live to be adults. Most of the

cyanotic patients do not survive the period of growth. The few that do are almost always free of symptoms of heart failure and have relatively small hearts.

TREATMENT

The treatment of congenital heart disease differs little from other forms of heart disease. Control of activity to avoid deterioration of functional capacity is important. There is no indication for more restriction than is necessary to avoid heart failure, however, and a careful, continuous study of each patient is essential in order to guide activity properly.

Protection of the patients against infection is important, especially in childhood. Every infectious disease is a major hazard and must be treated as a very serious complication regardless of how insignificant it appears at the outset.

Patent ductus arteriosus has been corrected many times surgically. The operative mortality is not excessive in experienced hands. An attempt should be made to ligate a patent ductus in every case which shows serious functional impairment and in cases in which subacute bacterial endocarditis is present. Several cases of subacute bacterial endocarditis which have been cured by ligation of a patent ductus arteriosus are on record. Ligation of every patent ductus arteriosus may be desirable, but more experience with the operation and a better knowledge of the operative mortality should be available before such treatment is recommended.

SUMMARY

Most cases of congenital heart disease may be placed in one of four groups corresponding to a single prominent, easily recognizable physical sign.

1 Cases with a systolic murmur at the left border of the sternum. This group includes cases with one or more of the following lesions: Interventricular septal defect, pulmonary stenosis, transposition of the great vessels and a few other rare anatomical lesions. The prognosis and management of cases within this group is more closely related to the degree of physiological disturbance than to the specific anatomical lesion.

2 Cases with cyanosis. This group includes cases with large shunts from the right to left side of the heart, cases with smaller shunts and right heart failure, and a few other severe lesions. In general the prognosis is poor in these cases. The few cases which

do well have little enlargement of the heart and few symptoms of lowered cardiac reserve.

3 Cases with the continuous murmur of patent ductus arteriosus

4 Cases with arterial hypertension in the arms but not in the legs These patients have coarctation of the aorta

This simple grouping includes the most common lesions Other lesions are uncommon or not recognizable before death

In infancy the diagnosis and prognosis of congenital heart disease is much less satisfactory than in older children and adults The greater severity and complexity of lesions, the inconstancy of physical signs, and the greater difficulty of physical and laboratory examination all increase the difficulty

THE SIGNIFICANCE OF GASTRO INTESTINAL TRACT ABNORMALITIES AS RELATED TO THE MANAGEMENT OF CARDIAC DISORDERS*

CLARENCE F G BROWN M.D.,† and RALPH E. DOLKART M.D.‡

PRIOR to Herrick's recognition of coronary occlusion as a disease entity, and prior to the availability of the electrocardiogram as an adjunct in diagnosis, "acute indigestion" was an acceptable cause of death. Although we now use the term coronary occlusion, the tendency for occurrence following over-eating is still an accepted phenomenon. In recent years an ever-increasing emphasis is being placed upon the interrelationship between reflex phenomena involving the cardiovascular and gastro-intestinal systems.

CHRONIC GALLBLADDER DISEASE

Willius and Fitzpatrick¹ almost twenty years ago reported that 39 per cent of patients with chronic gallbladder disease had associated changes of the cardiovascular system, coronary artery sclerosis being the most common in occurrence. More recently Ravdin and his co-workers have attached considerable importance to these concomitantly occurring disease entities and recommend cholecystectomy in patients who have symptoms of angina and in whom pathologic gallbladders can be demonstrated. Although Maisel and Alvarez² report that there is no proof that biliary tract disease has any direct influence in the production of heart disease, in our opinion the clinical problem does not revolve around the presence or absence of such a relationship. Rather, if the presence of gallbladder disease acts as a reflex trigger mechanism through which the frequency of anginal attacks is increased, then removal of the associated ab-

normality, the gallbladder, is a constructive step in therapy. Studies by Woollard, Ankep and Stacey, Mann, Wiggers, and others would seem to indicate that the coronary arteries are dilated by sympathetic impulses of adrenalin, and constricted by the vagus.³ It is probably through mediation with such reflex connections that gallbladder abnormalities alter the course of individuals with coronary artery disease.

From a clinical point of view, careful study and search for gallbladder disease should be made in the case of individuals who manifest food intolerances, have associated stomach or bowel distress as indicated by gaseous distention after meals, or upper right quadrant distress, together with evidence of coronary artery disease. Not uncommonly, there may be variations from the usual sites of pain radiation or pain reference of both cardiac and gallbladder origin. Surgical removal of the gallbladder in properly selected risks is definitely indicated not only in our own experience but in the cumulative case reports in the literature.

Individuals who are not proper surgical risks should be managed with care and caution with a view toward minimizing the reflex stimuli arising from the gallbladder. These principles we have previously discussed.^{4, 5} Briefly they entail consistent use of antispasmodic drugs, preferably tincture of belladonna or atropine up to the point of atropinization consistent with the patient's welfare and comfort, dietary control, use of a frequent-feeding bland diet, of low-caloric content with an obese patient, avoidance of cooked fats but use of uncooked fats within limits of fat tolerance as discussed by Ivy, use of oxidized bile salts, again dependent upon the patient's tolerance. Frequent feedings may still be achieved in obese patients through the use of gelatin feedings between meals instead of foods with higher caloric content.

HIATUS HERNIA

Hiatus hernia is a second category in which there is considerable interrelationship between the cardiac and gastro-intestinal systems. Not infrequently substernal pain radiating to the shoulder may be a presenting symptom of hiatus hernia which is commonly misinterpreted as of coronary artery origin. Exertional dyspnea may be present but may result from reduction of vital capacity due to the presence of a large amount of the stomach in the chest. Other cardiac symptoms may be the result of rota-

tion or displacement of the heart or from increased intra-abdominal pressure from below. The foregoing indicate the mechanical aspects of hiatus hernia which may mimic heart disease. Both conditions may occur together and in such instances there is no doubt a reflex trigger mechanism as in gallbladder disease which accentuates the frequency or degree of coronary artery spasm. Treatment of hiatus hernia is largely in either of two categories—surgical repair or palliative. Small frequent feedings, careful observance of an upright posture during and considerably after the ingestion of food, and use of antispasmodics.

It is interesting to note that more frequently symptoms from a hiatus hernia develop in later life. The age incidence of the group reported by Murphy and Hoy⁸ was in the third decade of life or beyond. It is our impression that the occurrence of symptoms in later years even though the abnormality probably existed for a considerable period of years, if not at birth, may be explained by reduction in threshold levels for visceral stimuli or because of increased changes in the blood vessels themselves.

IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome or nervous indigestion is by far one of the commonest gastro-intestinal tract abnormalities. It is our opinion that almost any intra-abdominal viscus may initiate reflexes which may affect the coronary circulation, heart rate or rhythm. It is well established that actual torsion or simple tension from any cause which twists or pulls a viscus sets up visceral reflexes which affect the entire circulatory system.

In searching for causes of coronary embarrassment, the abdominal organs classed as the hollow visci are the more frequent offenders. Emptying an over-full urinary bladder many times relieves a dull precordial discomfort. In a spastic bowel, relief of chest pain is often achieved by a redistribution of the gases or by a bowel movement with free expulsion of gas and resultant lowering of the intraluminal pressure thresholds. All of these phenomena are increased by the presence of organic changes in the wall of the intestine. In diverticulosis increased production of reflex stimulation may result when there is mechanical embarrassment in one or more of the diverticula which is further increased when an actual diverticulitis is present with actual inflammation and concomitant colon spasm wherever it occurs.

Gilbert, Fenn, and LeRoy⁷ as well as others have demonstrated definite vasoconstriction of the coronary arteries upon distention of an inflated balloon in the stomach. Distention of the free abdominal cavity with air also caused constriction of the coronary arteries, which did not occur if the vagi had been cut or if atropine had been administered. They believe the latter phenomenon is an explanation of the relief of an anginal attack occurring in a patient whose abdomen is distended with gas, by the passage of flatus or belching.

It is equally interesting to correlate the high incidence of all types of sudden vascular accidents with either the desire to defecate or during or immediately after the bowel movement. This formerly was considered to be "straining at stool," but as many occur with just the urge to defecate and happen while the patient is on his way to the toilet. In this connection one of us has recently seen a patient hospitalized for a cataract extraction who had a coronary occlusion on his tenth postoperative day following the administration of a large saline purgative. Possibly with any radical change of intraluminal pressure thresholds of the hollow visci there is a general vascular repercussion and readjustment which brings out defects in the coronary arteries or any portion of the cardiovascular system. Careful observance of physiologic principles of bowel management obviously is indicated. It cannot be stressed too strongly that functional disorders should be evaluated and treated inasmuch as they predominate in bringing out the early pathologic manifestations via the route of visceral reflexes.

RAPID ENLARGEMENT OF LIVER WITH RIGHT HEART FAILURE

The last entity we should like to consider is one we have previously mentioned⁸ and which Boyer and White⁹ have recently discussed, namely rapid enlargement of the liver associated with right heart failure. This is well borne out in individuals with a marked kyphoscoliosis with heart failure due to chest deformity and reduction in vital capacity. Right heart failure occurs in the great majority of these individuals, and right upper quadrant pain is one of the earliest symptoms. Apparently enlargement of the liver with distention of Glisson's capsule produces a sensation of fullness and pressure in the abdomen and frequently with severe and intense right upper quad-

rant pain Kuntz believes that pulling down on the attachment to the diaphragm is also an important mechanism

SUMMARY

The interrelationship of reflex phenomena between the abdominal viscera and the cardiovascular system have been indicated. Therapeutic efforts must be directed toward physiologic control of the gastro-intestinal as well as the cardiovascular systems

DISSECTING ANEURYSM OF THE AORTA*

EMMET B. BAY, M.D.†

DISSECTING aneurysm of the aorta rivals syphilis in the number and variety of other disease entities which it may simulate and with which it may be confused. In the large and growing literature‡ on the subject it is apparent that it is most often misdiagnosed coronary thrombosis. It has also been mistaken for syphilitic aortitis, cerebral vascular accidents, mediastinal tumors, pneumonia, diaphragmatic hernia, cholelithiasis, pancreatitis, nephrolithiasis, ruptured peptic ulcer, mesenteric thrombosis, embolic occlusion of the arteries in the extremities and disease of the lower spinal cord.

The incidence of dissecting aneurysm in general is not available but though low, it appears to be large enough to warrant inclusion in the thinking of a physician attempting the diagnosis of an acute, severe chest or back pain in an older patient. As a cause of sudden death, Mote and Carr¹ found it in about 11 per cent of nontraumatic coroner's cases. The number of cases correctly diagnosed ante mortem is increasing rapidly and represents from 10 to 30 per cent of most of the series reported.

PRECIPITATING FACTORS

It occurs much more frequently in men than in women and usually in patients with *pre-existing hypertension*. Syphilis of the aorta is not an important predisposing factor nor is external trauma as frequent a precipitating factor as was formerly thought.

The role of *unusual exertion* in its onset is not yet a settled point. Cherry and Cherry² believe that on a statistical basis exer-

* From the Department of Medicine, University of Chicago School of Medicine.

‡ No attempt is made to be all-inclusive in the appended bibliography. For an excellent historical account of our knowledge of this disease and a good bibliography the reader is referred to an article by Flaxman in the *American Heart Journal*, 24:654, 1942.

tion is a coincidental rather than a necessary precipitating factor. This, of course, has important medicolegal connotations. There are case histories available, however, which suggest strongly that, in the presence of a background for trouble, excessive exertion is dramatically related to the beginning of symptoms.

ETIOLOGY AND PATHOLOGY

The pathogenesis probably includes two main modes of development. Erdheim's³ medial necrosis is the primary lesion in some cases and results in dissection by virtue of hematoma formation within the wall of the aorta brought about by rupture of the vasa vasorum. This subsequently may break through the intima in one or more places.

Primary rupture of the intima and subsequent dissection of the media also occur in the absence of pre-existing medial necrosis. Such intimal tears may occur without dissection and have been labeled incomplete rupture of the aorta by Gallavardin and Gravier⁴ and Peery.⁵ The latter states that this lesion is probably more frequent than dissecting aneurysm although it has not so far been diagnosed ante mortem.

Secondary pathologic changes serve to explain many of the mistakes in ante-mortem diagnoses, as was pointed out by Crowell.⁶ The intimal tear, with or without medial necrosis, may occur at any point along the aorta but more often is found in the ascending aorta near the aortic ring and frequently in that portion of the wall within the reflected pericardial sac. The subsequent dissection may travel in either or both directions up and down the aorta as well as around it. Its encroachment on the branches of the aorta and on the aortic ring produces the varied symptomatology which at once makes its diagnosis possible in an increasing number of cases and serves to confuse it with the wide range of clinical entities cited above. It may, for example, result in a suddenly developing aortic insufficiency by one of three mechanisms described in the literature. It may result in the partial or complete occlusion of one or more coronary, subclavian, carotid, intercostal, renal, mesenteric or common iliac arteries. The vessel or vessels involved determine the signs and symptoms produced.

Death may come suddenly when the dissecting aneurysm or the incomplete rupture of the aorta breaks through the adventitia. There are cases on record, however, in which survival of

such an accident has occurred, at least for a few days. The rupture may occur into the pericardial sac with resulting cardiac tamponade or into the pleural space, the mediastinum, the abdominal cavity, the retroperitoneal tissues, or even into the gastro-intestinal tract and be accompanied by the vomiting of blood

DIAGNOSIS

SYMPTOMS—Although “silent” dissections of the wall of the aorta are thought to occur, by far the majority of those which result in survival are accompanied by *pain*. This pain is often excruciating, unrelieved by large doses of morphine. It frequently resembles the distress in the chest produced by coronary thrombosis but does not radiate to the arms characteristically. It does tend to radiate to the back between the scapulae and sometimes to the neck and head, lower back and legs. Occasionally it travels, hour by hour or day by day, down the back from the neck to the legs. It may be throbbing in character and intermittent, lasting a few hours at a time.

Other symptoms, not invariably present, include dyspnea, vomiting, loss of consciousness, transient paralysis of the legs and in some instances those of heart failure. Rarely, hematuria has been prominent enough to suggest primary renal pathology.⁷

PHYSICAL FINDINGS—On physical examination there may be little to find which differs from the pre-existing record when such is available. The *blood pressure*, usually elevated previously, does not drop unless the patient develops the signs and symptoms of shock or unless the orifice or first portion of the artery in the extremity tested has been involved in the dissection. In the latter instance, the drop in blood pressure in one or two extremities and not in the others, in the presence of chest and back pain, points the way to a correct diagnosis.

The sudden development of the *diastolic murmur of aortic insufficiency* accompanied by the increased pulse pressure and other peripheral manifestations of this lesion within a day or two after the onset of chest and back pain is another clue strongly suggestive of the true nature of the pathology present when it occurs.

Transient changes in the strength and reflexes of one or both lower extremities when other symptoms of a dissecting aneurysm exist help to make the diagnosis definite.⁸

In those instances in which the patient lives for months or years after the onset, there may be remarkably little to show for it on physical examination or the signs of gradually developing heart failure may supervene

X-RAY STUDY—Among the laboratory procedures, roentgenography and fluoroscopy of the chest are the most helpful. A generalized widening of the aorta, especially in oblique views, is the characteristic finding. Occasionally this may include a widening of the vessels of the upper mediastinum

ELECTROCARDIOGRAPHY—The electrocardiogram usually does not change materially unless the coronary orifices are involved in the dissection. This negative finding is of some help in the differential diagnosis. In the event the coronaries are obstructed the electrocardiogram may follow the patterns of myocardial ischemia seen in coronary thrombosis and is likely to lead to a mistaken diagnosis unless some of the other main branches of the aorta are similarly affected in a way which reveals that the primary difficulty is in the aorta rather than in the coronary arteries

TESTS FOR SYPHILIS—The Wassermann reaction and other serological tests for syphilis when positive likewise serve more often than not to confuse the diagnosis. This is especially true when the dissection results in the development of aortic insufficiency.⁹ When it can be ascertained to be the case, the sudden onset of the latter helps to distinguish between luetic aortitis and dissecting aneurysm involving the aortic ring

PROGNOSIS

The course of this disorder varies from sudden death at the onset to more or less asymptomatic survival for several years in a few instances. It is probable that, as in the case of coronary thrombosis, prognoses will become somewhat more favorable as diagnoses improve. It will always have to be regarded as a serious accident to the cardiovascular system

TREATMENT

The treatment consists in rest in bed during the acute stage, with whatever sedation proves necessary to keep the patient as comfortable as may be. Repeated doses of morphine are frequently indicated but the smallest amount should be used which will suffice to relieve the pain.

Perhaps the most important feature of the treatment rests in making a diagnosis which will preclude surgical interference for various supposed colics or arterial emboli

PRESENTATION OF CASES

With these considerations in mind the seven cases found at autopsy at the University of Chicago Clinics during the first fifteen years of operation were reviewed. Only two of these cases were correctly diagnosed during life. In the presentation of these cases, special attention will be given to findings in the histories which might have led to a correct diagnosis in those instances in which it was missed.

CASE I—The patient was a white man seventy-three years old in April of 1929 when he was first seen. He had a history of herpes zoster involving the left leg in September, 1928, at which time diabetes was also diagnosed. He complained of residual pain in this leg. Nothing was found on examination germane to this discussion except a blood pressure of 170/90. Two years later he was seen again complaining of intermittent claudication and no pulse could be found in either dorsalis pedis or posterior tibial artery. Two months later he complained of mild pain in the arms and back. Three months later (August 31, 1931) he entered the hospital complaining of substernal pain of eight hours' duration and radiating down both arms. The findings were essentially unchanged except for the blood pressure, which was 150/98. Three days later a pericardial friction rub was heard and the blood pressure was 110/70. Electrocardiograms were typical of coronary thrombosis and this diagnosis was made. The patient died suddenly six days later.

Autopsy revealed 270 cc of blood in the partially obliterated pericardial sac. There was an occlusion of the circumflex branch of the left coronary artery and a myocardial infarct which had ruptured. An incidental finding was a very small (1 by 3 cm) dissecting aneurysm 5 cm above the bifurcation of the aorta. The material in this aneurysm included necrotic debris as well as discolored blood and it was presumed to be old.

Comment—The cause of death was properly diagnosed in this case but there was an additional finding—the small dissecting aneurysm near the end of the aorta, which appeared much older. Even if the assumption be made that it was somehow concerned in the production of his leg pains it is extremely doubtful that a correct diagnosis could have been made. There was no history

of low back pain of any severity and there were ample reasons for leg pain in the shape of arteriosclerosis and a history of herpes zoster

CASE II—This white man of sixty-eight had a history of anginal pain radiating to the right arm for one year before he was first seen on June 26, 1931. His heart was slightly enlarged and his blood pressure was 145/96. Electrocardiogram revealed what we would now call "left ventricular strain." Roentgenography and fluoroscopy showed a dilated, tortuous senile aorta with calcified plaques in the knob. There was some doubt as to whether the first portion of the aorta was sufficiently dilated to warrant the diagnosis of aneurysm, and the roentgenologist who first raised the question decided against it at a later visit. He had two attacks of precordial pain, dyspnea and cyanosis lasting for hours, one on July 25, 1931, and one September 15, 1933. These were diagnosed as coronary occlusions. After the last one he had symptoms of heart failure until his death March 19, 1934.

Autopsy revealed a generalized arteriosclerosis with marked calcification and narrowing of both coronary arteries. There was disseminated and focal fibrous scarring of the myocardium with beginning aneurysmal dilatation of the apex of the left ventricle (probably small healed infarcts). There was general dilatation of the ascending aorta and medial necrosis and rupture in the arch with the formation of two small dissecting aneurysms (one 1.5 cm., the other 8 mm. in its longest diameter). These small aneurysms were filled with laminated organizing blood clots.

Comment—Again the cause of death was properly diagnosed but the existence of incomplete rupture of the aorta with small dissecting aneurysms was unsuspected during life. It is possible that one or two of his attacks of anginal pain differed in character or radiation sufficiently to make the alert physician suspect some such episode but this does not seem at all likely. On a statistical basis multiple sites for the origin of variable coronary pain would be much more probable.

CASE III—The patient, a white man aged fifty-one years, was first seen August 26, 1932, complaining of dizziness, especially when stooping. His blood pressure was 188/128 and the aortic second sound was ringing although he was said to have had a normal blood pressure two years previously. Cardiac and renal functions were within normal limits at this time. He had no other symptoms until March 23, 1934, when he noticed an occasional desire to sit up in

bed to breathe freely. By January of 1935 he had frank symptoms of myocardial insufficiency. He entered the hospital March 8, 1935, complaining of dyspnea, weakness, cough and frontal headaches. His blood pressure was 224/184 and the pulse rate was 120 per minute. The heart was only slightly enlarged to percussion and a systolic murmur was heard both at the apex and base. He was markedly orthopneic. There was a definite pulsation in the epigastrium synchronous with the heart beat. Kidney function was now reduced by the urea clearance test to about 50 per cent of normal. On his last day of life, March 15, 1935, he failed rapidly and the blood pressure gradually dropped to 92/70 just before death. The clinical diagnosis was malignant hypertension with myocardial and renal insufficiency.

Autopsy revealed arteriolar nephrosclerosis with marked cardiac hypertrophy and marked atheromatosis of the large and medium sized arteries. There was an early bronchopneumonia. The abdominal aorta had more atheromatosis than the thoracic aorta and contained an occasional fibrous patch. Microscopically there was one early thrombus in the media of the abdominal aorta in an area representing the beginning formation of a dissecting aneurysm.

Comment—The anatomic diagnosis confirmed the clinical diagnosis of malignant hypertension. Although the microscopic findings permitted the pathological diagnosis of early dissecting aneurysm the presumption is high that this lesion was terminal and asymptomatic and hence not capable of diagnosis during life.

CASE IV—This patient was a forty-three-year-old white man who was first seen on July 2, 1935, complaining of "kidney trouble." Three years previously he had had swelling of the eyelids and ankles diagnosed nephritis elsewhere. For six months he had noted an increasing shortness of breath. Off and on during the three years he had had a pain in the back of the neck, pounding in character and synchronous with the heart beat. Examination revealed a pale, dyspneic man whose heart was enlarged and whose blood pressure was 215/130. His hemoglobin was 50 per cent and his red blood count was 2,190,000. The urine showed albumin 4 plus, a few red blood cells and occasional hyaline and granular casts. Renal function was 10 per cent of normal.

The patient was hospitalized on July 10, 1935, and improved slightly thereafter until the evening of July 17, when he suddenly developed an excruciating pain between his shoulder blades. Five minutes later the pain radiated to the precordium and left arm. He

was more dyspneic and somewhat cyanotic. He was given $\frac{1}{4}$ grain of morphine, repeated in twenty minutes, and two hours later $\frac{1}{6}$ grain. His blood pressure at first was 254/148. The next day it was 224/132 at 8 00 A. M., 228/130 at 10 00 A. M., 226/128 at 12 00 M and 228/126 at 5 00 P. M. During this day he received $\frac{3}{8}$ grain of morphine and was drowsy and partially disoriented. Without further sedation he remained completely disoriented until July 23, although his blood pressure remained between 224 and 242 systolic and between 114 and 136 diastolic. On July 23 he complained of more pain in the chest and back and was given two doses of morphine, each $\frac{1}{4}$ grain. The next day he developed a loud pericardial friction rub. The next day, July 25, 1935, his blood pressure dropped for the first time to 152/84 and he died at 3 50 P. M. The clinical diagnosis was chronic diffuse glomerulonephritis, renal and myocardial insufficiency, and dissecting aneurysm of the thoracic aorta.

Autopsy revealed chronic glomerulonephritis and hypertrophy of the left ventricle of the heart. There was a transverse rupture of the aorta at the arch with an organized peri-aortic hematoma and a dissecting aneurysm arising at the point of rupture and extending distally 2 cm. There was a uremic pericarditis.

Comment—The correct ante-mortem diagnosis was made in this case in spite of a strong suspicion of a coronary thrombosis largely because the blood pressure failed to drop, the electrocardiogram was not characteristic of coronary occlusion and the pain started in the back between the shoulder blades. The diagnosis, made originally by an assistant resident, was the more commendable in the face of the facts that within five minutes the pain had largely shifted to the precordium and radiated down the left arm, a frank pericardial friction rub developed later and lastly, the terminal uremic disorientation made the symptomatology vague.

CASE V—This white man entered the hospital on July 6, 1936. That morning at 6 45 he was seized with a sharp, stabbing pain over the left cheek which radiated to the back of the neck and down the spine to about the 8th thoracic vertebra. The pain in the back persisted as the pain in the jaw subsided. Later in the day he developed "pin-pricks" in the right arm. There was no sternal or precordial pain. He had no knowledge of pre-existing trouble. On examination little was found except a blood pressure of 176/120, a white blood count of 13,200 and sugar 2 plus in the urine. That evening he suddenly stopped talking in the middle of a sentence, became unconscious and his systolic blood pressure fell to 72. The

next day his blood pressure was 110/98 and an electrocardiogram was not characteristic of coronary thrombosis. Chest roentgenograms taken on a "pneumonia bed" showed a widening of the mediastinal shadow, diagnosed as an aortic aneurysm by the roentgenologist. The blood pressure on the next day was 128/88 in the left arm and 130/90 in the right. He still had pain across the shoulders. He suddenly expired at 4 30 A. M. the next morning (July 9, 1936). The clinical diagnosis was dissecting aneurysm of the thoracic aorta.

Autopsy revealed a dissecting aneurysm of the aorta with aortic medianecrosis, and rupture of the aorta at the ring with hemorrhage into the pericardial sac, periaortic tissue and both pleural cavities. There was mild coronary atherosclerosis.

Comment—The correct clinical diagnosis was based upon the location and radiation of the pain (only in the back, never precordial), the lack of electrocardiographic change and the roentgenographic finding of widening of the aorta. The drop in blood pressure was misinterpreted as evidence of coronary thrombosis but this opinion did not prevail in the face of accumulating laboratory evidence to the contrary.

CASE VI—This patient, a white man aged sixty-eight years, entered the hospital on May 10, 1940. He had known of high blood pressure for six months. For four months he had had an increasing weakness, dyspnea and weight loss and had vomited for the first time the day before admission. On the day of admission he developed lower left chest pain of intense severity. On examination he appeared emaciated and sick. His heart was enlarged and there was a systolic apical murmur. His blood pressure was 220/148 and the heart rate was 112. One hour later there was a loud pericardial friction rub. Hemoglobin was 60 per cent, red blood count 2,880,000. The urine showed albumin 3 plus and a few hyaline casts. He was given morphine on three occasions during the first two days because of severe precordial pain and dyspnea. His blood pressure on the second day was 200/160 and on the third was 144/88. He became comatose and died on May 13, at 3 15 A. M. The clinical diagnosis was hypertensive cardiovascular disease and coronary thrombosis.

Autopsy revealed a chronic arteriolonephrosclerosis and chronic primary hypertension with marked concentric hypertrophy of the heart, acute serofibrinous uremic pericarditis and marked atherosclerosis of the aorta and coronary arteries. An early dissecting aneurysm was found in a microscopic section of the first portion

of the aorta. At this point there was a diffuse inflammation of the media characterized by the presence of polymorphonuclears and mononuclears as well as fibrinoid necrosis and a definite break in the intima and media.

Comment—In retrospect it is probable that the patient's severe precordial pain was that of uremic pericarditis and that the microscopic tear in the aorta had nothing to do with it. The mistaken clinical diagnosis of coronary thrombosis might have been avoided, too, if serial electrocardiograms had been taken. This was not done because of overconfidence on the part of the clinician in his early diagnosis and because the patient was continuously in an oxygen tent. Both of these are inadequate reasons. The dissecting aneurysm was probably too small to permit of an ante-mortem diagnosis although not enough is yet known about the degree of pain such a lesion can produce.

CASE VII—This white man of fifty-two years entered the hospital on January 29, 1942, complaining of shortness of breath and edema of the ankles of seven months' duration. A physician who saw him before admission had found a blood pressure of 240 and had put him to bed for a time. His symptoms increased in severity and included a cough and some vertigo on admission here. He had had low back pain for an indefinite but "long period" of time which had become much worse during the month preceding his admission. This pain did not radiate but was at times "very severe." On examination he was a very obese, worried patient with some orthopnea. The heart was enlarged, there were systolic and diastolic murmurs at the base and the blood pressure was 256/110. Respirations were 30 per minute. There was a pitting edema of the ankles. Albumin and casts were found in the urine. He was treated for heart failure and lost 20 kg. in nineteen days. He was discharged subjectively improved with a blood pressure which averaged 190/115.

The patient re-entered the hospital on April 27, 1942, complaining of the same symptoms, i.e., dyspnea and edema of the ankles and a cough. He had seen clotted blood in the urine on two or three occasions two weeks before this admission. He had also had frequent, severe aches in the right flank. His condition remained unchanged until May 4, 1942, when, at 3 00 A. M., he developed a pain "in the left shoulder blade" and felt "different than he had ever felt." Morphine gave temporary relief but he was found dead in bed at 1 00 P. M. His blood pressure had dropped from 200/110 to 160/95 and then returned to 200/120 on this day. The clinical

diagnosis was hypertensive cardiovascular disease with a terminal coronary occlusion.

Autopsy revealed a large transverse laceration of the ascending aorta just above the valve and a dissecting aneurysm extending the entire length of the aorta, into both common iliac arteries and out along the right renal artery. There was a tear through the adventitia of the ascending aorta with hemorrhagic infiltration of the mediastinal tissues and a massive, fatal hemopericardium (cardiac tamponade). Although there was marked aortic sclerosis, sections showed only a very mild medial degeneration. Embolic occlusion of a left renal branch and of a branch of the splenic artery had occurred. There was profound atrophy of the cerebral cortex.

Comment—The terminal event in this patient's illness might have been suspected if more attention had been paid to the location of his pain, the recovery in his blood pressure and possibly to the gross hematuria occurring two weeks before death. The latter symptom, however, might well have been the result of the embolic occlusion of the renal artery found postmortem. His great obesity (he weighed 133.4 kg [293 pounds]) and his clouded sensorium contributed to the difficulty. The one made for technically unsatisfactory chest roentgenograms, the other for doubt about the location, duration and severity of his low back, right flank and later, left scapular pain.

SUMMARY AND CONCLUSIONS

Some helpful leads to the making of a correct ante-mortem diagnosis of dissecting aneurysm of the aorta have been gathered from the literature. These may be epitomized by saying: When severe pain, especially upper back pain, is accompanied by cerebral symptoms, a change in the blood pressure of one extremity only, hematuria, transient paralysis of the legs, no electrocardiographic changes, a widened aorta or a suddenly developing aortic insufficiency, dissecting aneurysm should be suspected.

Seven cases found at autopsy have been reviewed. In four the diagnosis was not made and most probably could not have been made. In two the ante-mortem diagnosis was made correctly. In one the condition was not suspected when there were some hints of the type mentioned above which were overlooked.

A SURVEY OF RHEUMATIC FEVER IN A LARGE STATION HOSPITAL*

CAPTAIN MARTIN H WENDKOST† and MAJOR JOHN NOLL, Jr‡
Medical Corps, Army of the United States

BECAUSE of the average age of the military recruit it is to be expected that acute rheumatic fever would not be infrequently encountered among those in the armed forces. Unfortunately, its detection is not always easy, for as Paul¹ states "The concept of rheumatic fever as an entity has slowly emerged from a group of joint diseases and as a matter of fact it is still not completely free, for there are certain bonds which entangle it with the poorly understood disease—rheumatoid arthritis." He therefore takes the view, with which we thoroughly concur, that since heart disease is an integral part of the rheumatic fever picture, the recognition of active involvement of the heart in cases of acute polyarthritis should help to identify the acute rheumatic state. Unfortunately, in our experience, and in that of others,^{2 3, 4} in adults with acute migratory polyarticular rheumatism the clinical expression of active carditis such as significant murmurs or cardiac enlargement, even when the latter is sought for with the aid of the teleoroentgenogram, has frequently been lacking. Under such circumstances it is therefore to be expected, considering the high incidence of electrocardiographic abnormalities which have been recorded in various surveys^{3 5 6 7, 8 9 10} among patients with clinically recognizable acute rheumatic heart disease, that in a random group with

‡ Chief of Medical Service, Station Hospital, U S Army, Chicago

acute polyarthritis the information obtained from serial curves should offer an excellent objective means for differentiating rheumatic fever from other simulative diseases. The purpose of the present study is an attempt to test the validity of this view and to correlate other pertinent data bearing on the problem of acute rheumatic fever, as it is encountered in the military services

MATERIAL AND METHOD

During the period from January 1 to July 31, 1943, 135 soldiers, in whom acute migratory polyarticular rheumatism was the outstanding syndrome, were admitted to the Station Hospital, AAFTHC, Chicago. In most instances the arthritis was the primary cause for the hospitalization, but in occasional cases the original complaint was an acute upper respiratory infection, the arthritic manifestations becoming evident after the entry of the patients to the hospital. In the present study, beginning with the first such case, 100 consecutive admissions for acute polyarthritis were carefully analyzed. In this random group, all were young male adults who had been carrying on their usual military duties prior to the onset of their illness. Their ages ranged from eighteen to forty years, 81.4 per cent being thirty years or less in age. Because the findings obtained in this survey have served to establish the diagnostic criteria and epidemiological correlations subsequently applied to the entire series, the details of the method will be briefly described.

On the day of admission a complete history was obtained, especial emphasis being placed on the date of onset of the arthritic symptoms, the number of joints involved, the frequency of antecedent attacks of rheumatic infection, the presence or absence of cardiac pain, the location of the soldier at the time of onset of the arthritis, the home location, the familial incidence of rheumatic infection or rheumatic heart disease, and knowledge of any previous tonsillectomy. The same day a complete physical examination was performed by the authors, especial search being made for infected tonsils, joint disease, subcutaneous nodules, purpura or erythematous lesions, cardiac enlargement, adventitious sounds such as friction rub or murmurs, changing quality of the heart sounds, any irregularity of rhythm, a triplication of sounds in each cardiac cycle, and signs of cardiac failure.

Each subject was examined in the supine, sitting and lateral positions, before and after exercise, and with the breath held in various phases of respiration. This practice was found useful in identifying some of the conduction disturbances and in classifying a murmur. All diastolic murmurs were considered significant. However, because of the frequent finding of functional low-pitched systolic murmurs in healthy young adults, a systolic murmur was considered to be of organic origin only if it did not vary greatly with respiration, if it persisted in various body positions, if its maximum intensity was at the apex, if it was long and took up most of systole, if it was high pitched and had a swishing quality, and if it persisted throughout the period of observation.

Routine laboratory studies within the first twenty-four hours after the initial examination consisted of a urinalysis, complete blood count, erythrocyte sedimentation time, teleoroentgenogram and an electrocardiogram. Except in special circumstances, another electrocardiogram was not obtained until the following day. Afterwards, unless more frequent use of those laboratory procedures seemed to be warranted, further electrocardiograms and erythrocyte sedimentation determinations were obtained at weekly intervals.

An examination similar to the original one was conducted at frequent intervals by the authors during each patient's hospital stay.

All electrocardiograms were obtained with the patient in the recumbent position. Unless otherwise indicated, Lead CF-4 was the chest lead usually employed. Any changes noted could not be attributed to a drug because acetylsalicylic acid was the only medication administered to these patients.

The effect of a single large dose of atropine sulfate was also noted in several instances, serial tracings being obtained at ten-minute intervals within an hour after the subcutaneous administration of 2.5 mg. of this drug.

A portion of this study is an attempt to correlate the incidence of hemolytic streptococcal infections with that of rheumatic fever and scarlet fever. The criteria for the diagnosis of the latter disease consisted of the finding of a punctate, erythematous rash, a diffusely injected throat, pastia lines, circumoral pallor, coated tongue with denuded edges or a "strawberry" tongue later developing a "raspberry" appearance, all of which

would be followed by desquamation of the skin. In doubtful cases a Schultz-Charlton test was done.

THE DIAGNOSIS OF ACTIVE RHEUMATIC CARDITIS

In this series of 100 consecutive admissions exhibiting the syndrome of acute migratory polyarticular rheumatism, involvement of the heart was detected in 69 per cent. The means by which this was accomplished are discussed in detail below.

A. Physical Signs

These can broadly be placed in three categories, namely, those indicative of endocardial, myocardial and pericardial involvement. The detection of endocarditis was dependent on the elicitation of murmurs which could definitely be distinguished from the functional types that are so frequently heard among healthy young adults in the armed forces. The criteria for this distinction (v.s.) were rigidly adhered to, because it was believed that by this means errors would be minimized. The clinical detection of myocarditis could not be accomplished, in contrast with the situation in children, by the recognition of cardiac enlargement. More reliable for this purpose, it was discovered, was the identification of various disturbances of rhythm. The diagnosis of pericarditis was made in only one instance by the auscultation of the classical friction rub, even though 10 per cent of this series complained of precordial pain at one time or another during the illness. Despite the fact that the significance of a midsystolic click is of questionable diagnostic value,¹¹ a brief discussion of this adventitious cardiac sound is included because of its detection in two of the cases, manifesting other evidences of acute rheumatic heart disease. In the entire series active involvement of the heart could be *indisputably* recognized by clinical examination alone in a fairly large proportion, if signs of conduction disturbances rather than those of endocardial lesions are sought for (Table 3). This fact will become apparent in the more detailed analysis which follows.

1 *Significant Murmurs*—Adhering to the rigid criteria already described, significant murmurs were audible in only 17 per cent of this series. These were divided as follows: mitral systolic alone, 11 per cent, mitral systolic associated with an aortic diastolic, 4 per cent, and aortic diastolic alone, 2 per cent. It will be noted that no mitral diastolic murmurs were discov-

ered The correlation between the incidence of endocarditis and previous episodes of rheumatic infection can be stated thus Of the 17 per cent showing signs of endocārditis, only nine cases, roughly 50 per cent, gave a history of antecedent attacks of rheumatic fever Of the total number with clinical signs of endocarditis, 70 per cent (representing 12 per cent of this entire series) also showed substantiating electrocardiographic evidence of active carditis Stated differently, in the group in whom the presence of active carditis could be identified, this identification was based, in 72 per cent of the cases, on the recognition of an endocardial lesion alone On the other hand, in only 5 per cent of this entire series of 100 cases of acute polyarthritis the diagnosis of acute rheumatic heart disease was dependent purely on the finding of significant murmurs It should also be stated that in this group with endocarditis there was never any roentgen evidence of enlargement of any of the cardiac chambers

2. *Summation Gallop Rhythm*¹¹—In 35 per cent of this series, usually at an early stage of the illness, a transient prolongation of the P-R interval with normal sinus rhythm was recorded in the electrocardiogram In about one quarter of this number, a summation type of gallop rhythm was audible In some instances this could be elicited by accelerating the cardiac rate by mildly exercising the patient in bed There was no correlation noted between the severity of the first degree heart block and the findings of summation gallop rhythm The latter was never elicited in the absence of a first degree heart block

3 *Varying Intensity of the First Heart Sound*—This sign was found useful in detecting the presence of auriculoventricular dissociation and hence active carditis, because it was found in one half of six cases in which this evanescent disturbance of rhythm was recorded in the electrocardiograph It never was present in the absence of this particular conduction disturbance

4 *Dropped Beats*—In all of the six instances in which the diagnosis of partial heart block with a Wenckebach phenomenon and dropped beats was made by means of the electrocardiograph, it was possible to predict the diagnosis by the finding of dropped beats on auscultation of the heart This type of conduction disturbance usually was present only in the early stages of the disease Its confusion with premature contractions was always easily eliminated if one excluded prematurity of the sound preceding the pause and also if one carefully listened for

summation gallop rhythm in occasional cardiac cycles, following the pause

5 *Premature Contractions*—These occurred in 5 per cent of the series and, as would be expected, there was a uniform correlation between the electrocardiographic and the clinical findings. They were always isolated and never appeared as runs of paroxysmal tachycardia. They never persisted after the acute infection had subsided. None of them were interpolated so that their clinical detection was easy.

6 *Sinus Bradycardia*—This occurred in 24 per cent of the series and, as would be expected, there was a uniform correlation between the electrocardiographic and the clinical findings. In each instance the heart rate was accelerated by mild exercise, but never to the extent which would occur normally. With the patient holding his breath there was no variation in intensity of the first heart sound, such as one elicits in complete heart block with similar slowing of the heart rate.

7 *Pericardial Friction Rub*—This was heard in only one instance, and in this case there was also a significant systolic mitral murmur without associated cardiac enlargement or detectable pericardial effusion in the teleoroentgenogram. Although transient inversion of T waves in Leads II and III occurred in the electrocardiogram of this patient, in seven other cases significant T wave inversions occurred without an accompanying friction rub.

8 *Cardiac Enlargement*—This was never discovered by the usual methods of physical examination in any of these individuals, including the patient in whom the teleoroentgenogram was able to demonstrate a slight and transient increase in the cardiac diameters. No reliance can therefore be placed on the clinical detection of transient cardiac dilatation during the course of acute rheumatic fever in the young adult.

9 *Midsystolic Click*¹¹—This peculiar adventitious cardiac sound which was encountered in two of our cases had all the characteristics of an extracardiac phenomenon. It was localized to the cardiac apex in each instance. A striking characteristic was its marked accentuation with the subject sitting forward, disappearing with the subject in the recumbent position. This sound could easily be distinguished from the snappy first sound of mitral stenosis by the fact that it occurred in midsystole instead of early in systole, it became less intense rather than louder

when the patient assumed the left lateral decubitus position, and it was not associated with a mitral diastolic murmur. This sign is considered to be of questionable significance because it has been observed by the authors in normal young adults as well. On the other hand, in the two individuals in whom it appeared, other good evidence of cardiac involvement had been discovered.

B Electrocardiographic Alterations

The transient electrocardiographic abnormalities considered to be diagnostic of active carditis were arbitrarily divided into two groups, the *unequivocal* and the *equivocal* (Tables 1 and 2). The former consisted of first degree heart block, with the P-R interval measuring 0.22 seconds or more, partial auriculoventricular heart block with a Wenckebach phenomenon and dropped beats, auriculoventricular dissociation, inversion of the T waves in leads other than Lead III, bundle branch block, S-T interval deviations, and transient notching of the P waves in Lead I. The equivocal alterations consisted of temporary sinus bradycardia, the rate ranging from 41 to 58, other types of T wave changes, such as blunting and notching of the apex or tall upright T waves in Lead CF-4, the height exceeding 10 mm, transient diminution of the QRS complexes without change in the electrical axis, premature contractions of nodal, ventricular or auricular origin, wandering pacemaker, and transient shift of the electrical axis to the left.

The reasons for this differentiation are that the changes in the latter group, although considered significant by many authorities, are not so considered by others. The alterations in both groups were of a transient nature and all of them usually, but not always, disappeared after the clinical manifestations of the acute stage of this infection had subsided. The influence of heightened vagal tone upon the conduction disturbances was demonstrated by the fact that, in all cases in which the experiment was tried, they were abolished following the administration of atropine sulfate (Table 4). No correlation was found to exist between the severity of the polyarthritis and the electrocardiographic alterations. Similarly, no correlation was found to exist between subjective symptoms such as cardiac pain or dyspnea and the electrocardiographic findings. The latter were not infrequently quite striking in those who had the fewest complaints. In spite of the fact that 64 per cent of this series

showed graphic evidences of acute myocarditis, a transient enlargement of the heart was noted in only one instance. Too, of this large number with positive electrocardiographic changes, residual valvulitis occurred in only 18.8 per cent.

Fig. 28 (Lead II) —Transient nature of prolongation of the P-R interval associated with normal rhythm in early rheumatic fever. *A*, Present on admission of patient. *B*, absent in afternoon of same day. *C*, present again the following day.

1 UNEQUIVOCAL CHANGES —(a) *Prolongation of the P-R Interval Associated with Normal Sinus Rhythm* —Of all the various electrocardiographic changes, this was the most frequent, occurring in 35 per cent of this series. It appeared early in the course of the disease and usually disappeared as other manifestations of the infection subsided. On occasion however its ap-

TABLE 4
EFFECTS OF ATRAPINE UPON HEART RHYTHM IN SIX CASES OF RHEUMATIC FEVER

Case No	Rhythm Before Exhibition of Drug	10 Min.	20 Min.	30 Min	40 Min.	50 Min	60 Min
1	Normal sinus mechanism with P R interval of 0.40 sec. Ventricular rate = 100	P R = 0.40 V.R. = 77.5	P R = 0.36 V.R. = 100	P R = 0.30 V.R. = 100	P R = 0.36 V.R. = 100	P R = 0.36 V.R. = 100	P R = 0.40 V.R. = 86
2	Normal sinus mechanism with P R interval of 0.40 sec. Ventricular rate = 67	P R = 0.40 V.R. = 67	P R = 0.36 V.R. = 67	P R = 0.28 V.R. = 83	P R = 0.28 V.R. = 83	P R = 0.34 V.R. = 88	P R = 0.36 V.R. = 83
3	Partial heart block with Wenckebach phenomenon—dropped beats			P R = 0.28 NSM V.R. = 94	P R = 0.26 NSM V.R. = 73	P R = 0.20 NSM V.R. = 79	
4	Partial heart block with Wenckebach phenomenon—dropped beats	Sinus rhythm Rate = 52 P R = 0.18	Sinus rhythm Rate = 136 P R = 0.18	Sinus rhythm Rate = 157 P R = 0.16		A V dissociation A.R. = 150 V.R. = 136	Sinus rhythm Rate = 136 P R = 0.18
5	Normal sinus mechanism with P R interval of 0.26 sec. Notched P wave in Lead I Ventricular rate = 88	Notched P P R = 0.20 V.R. = 115	Notched P P R = 0.02 V.R. = 125	P normal P R = 0.20 V.R. = 125	P normal P R = 0.20 V.R. = 125	P normal P R = 0.20 V.R. = 120	
6	Normal sinus mechanism with P R interval of 0.32 sec. Ventricular rate = 115	P R = 0.26 V.R. = 115	P R = 0.18 V.R. = 115	P R = 0.18 V.R. = 125	P R = 0.18 V.R. = 125	P R = 0.18 V.R. = 125	

Key P R = P R interval in seconds, V R. = ventricular rate A.R. = auricular rate NSM = normal sinus mechanism

pearance or persistence was the only detectable evidence that the acute rheumatic state had not disappeared. Its inconstant and transient nature was clearly demonstrated in one case in which this change was recorded in the electrocardiogram obtained on the morning of the day of admission (Fig 28, A), being absent in the afternoon of that same day (Fig 28, B) and then reappearing on the following day (Fig 28, C).

First degree heart block was an isolated finding in only 7 per cent of this series, leaving 28 per cent which were associated with other electrocardiographic alterations (Table 1). In four cases with this type of change, serial tracings were obtained following the subcutaneous injection of 2.5 mg of atropine sulfate, and in each instance there was a significant though temporary reduction in the auriculoventricular conduction time (Table 4). The first degree heart block in this series varied from 0.22 to 0.44 second. However, the extent of the myocardial involvement could not be predicated from the length of the P-R interval because frequently other serious changes in the electrocardiograms were encountered in association with P-R intervals of normal or only slightly increased duration.

(b) *Partial Auriculoventricular Heart Block with Wenckebach Phenomenon and Dropped Beats*—This finding, which was never an isolated occurrence, appeared in 6 per cent of this series. The associated changes are seen in Table 1. This conduction disturbance appeared early in the disease and was always a transient phenomenon, being only one component of the acute rheumatic state, never persisting after other evidences of the acute infection had disappeared. In the single case in this entire series in which the teleoroentgenogram demonstrated evidence of temporary cardiac enlargement, this type of disturbance in rhythm was encountered. This suggests that it is probably indicative of fairly severe myocardial involvement. The maximum length of the P-R interval associated with the Wenckebach phenomenon in these cases usually did not equal and never exceeded the auriculoventricular conduction time in many instances associated with first degree heart block and normal sinus rhythm. It was also observed in three individuals in whom a transient partial heart block with dropped beats was recorded, that during the stage of the partial heart block with Wenckebach phenomenon the maximum P-R interval was less than that which appeared when a normal sinus rhythm was subsequently re-

stored In the two cases in which the experiment was tried, this conduction disturbance was temporarily abolished by the subcutaneous administration of 2.5 mg. of atropine sulfate (Table 4)

(c) *Atriculoventricular Dissociation*—This disturbance in rhythm occurred in 6 per cent of this series. It was never an isolated finding, and usually appeared early in the disease. The other types of electrocardiographic abnormalities which either preceded or followed its appearance are seen in Table 1, but of these a prolonged P-R interval was a constant association. The ventricular rate encountered in this series with this conduction disturbance ranged from 65 to 100

(d) *Delayed Intraventricular Conduction*—It occurred only once and was manifested by a widened S pattern. The only associated change consisted of ventricular premature contractions

(e) *Delayed Intra-auricular Conduction*—This was manifested by a notched P wave in Lead I. It occurred only once. Interestingly enough, it was not present in the early tracings of this individual, but appeared only in subsequent serial electrocardiograms. It was temporarily abolished following the subcutaneous administration of 2.5 mg. of atropine sulfate (Table 4). Associated electrocardiographic changes are recorded in Table 1

(f) *T Wave Inversions*—These can be divided into two groups, namely, those occurring in the precordial lead alone (4 per cent) and those found only in the limb leads (4 per cent). Peculiarly enough, the two never coexisted. Among this 8 per cent the inverted T waves were an isolated finding in one half of this number. The changes associated with the other 4 per cent are listed in Table 1. In the limb leads, the inversion was noted in Leads I and II in one case, and in Leads II and III in the remainder. Eventually in all but one case the negative T waves disappeared, the time for this evolution varying from seven to thirty-nine days. In only one case of the entire group, the T wave inversion was preceded by an elevation of the S-T segment. In one case in which a negative T wave appeared as an isolated finding in Lead CF-4, the polarity of T became positive within several days and then subsequently without any other evidences of rheumatic activity, it again became negative, and shortly thereafter returned to its normal position. In one of the cases with inverted T waves in the limb leads a pericardial friction rub was audible, but x-ray examination failed to

show any enlargement of the cardiac shadow Too, there was no cardiac enlargement in the teleoroentgenogram in any of the other cases with T wave inversion Physical signs in the heart were lacking in the 4 per cent manifesting a negative T wave in the precordial lead In all cases in which this change occurred in Lead CF-4, the possibility of malposition of the exploring electrode in its production was always carefully excluded

(g) *S-T Segment Deviations*—These occurred in 2 per cent of the entire series In one instance they consisted of slight depressions in Leads II and III, being the only evidence of an acute myocardial involvement until a partial auriculoventricular heart block with a Wenckebach phenomenon appeared in subsequent tracings In this case no changes in polarity of the T wave were ever noted In the other instance the S-T changes consisted of elevations in Leads II and III, these were subsequently succeeded by inversion of T in these same leads In the latter case, no clinical evidence of pericarditis was ever noted An endocardial lesion was not manifest in either instance

2 EQUIVOCAL CHANGES—(a) *Sinus Bradycardia*—This occurred in 24 per cent of this series, being an isolated finding in only 5 per cent In this group the rate ranged from 41 to 58 per minute, eventually returning to normal in each instance The associated changes are listed in Table 2 Attention is invited to the large number of associated changes dependent on increased vagal tone, such as first degree heart block, partial heart block and auriculoventricular dissociation

(b) *Tall Upright T waves in the Precordial Lead (CF-4)*—Upright T waves exceeding 10 mm in the precordial lead were encountered in 18 per cent of this series They were an isolated finding in only 3 per cent, and almost always were an accompaniment of significant electrocardiographic alterations These are listed in Table 2

(c) *Blunted and Notched T wave in the Precordial Lead (CF-4)*—This finding appeared in 2 per cent of the series In neither instance was it an isolated finding Vagal effects such as sinus bradycardia and first degree heart block were accompanying disturbances in one instance, and in the other an inversion of T subsequently appeared (Table 2) The incorporation of a P wave in the T wave as a cause for this appearance of the T wave was considered but easily excluded in both instances

(d) *Diminution in Amplitude of QRS in the Limb Leads In-*

dependent of Changes in the Electrical Axis—This finding appeared in 14 per cent of this series, never occurring as an isolated phenomenon (Table 2) The significance of this change can be judged from the fact that of the entire group, 7 per cent manifested it in conjunction with a first degree heart block. It was never associated with evidences of pericarditis with or without effusion.

(e) *Premature Contractions*—These occurred in 5 per cent of the series, being an isolated finding only once (Table 2) The ectopic foci occurred in the auricle, the ventricle and the auriculoventricular node. In this series they never gave rise to a paroxysmal tachycardia. They never persisted after the beginning of the convalescent stage of the acute rheumatic state.

(f) *Wandering Pacemaker*—This occurred in 2 per cent of the series. Its significance, however, can be judged from the fact that in one case it was associated with an aortic diastolic murmur and in the other with a first degree heart block which later eventuated in an auriculoventricular dissociation.

(g) *Shift in the Electrical Axis to the Left*—This occurred in 11 per cent of this series, being an isolated finding in only 3 per cent (Table 2). Accompanying changes consisted or prolonged P-R intervals (7 per cent), auriculoventricular dissociation (1 per cent), inverted T waves in leads other than Lead III (2 per cent), sinus bradycardia (6 per cent), diminished amplitude of QRS (3 per cent) and sinus bradycardia (6 per cent). It was also striking that a shift in the electrical axis to the right was only rarely encountered.

C Symptoms Suggesting Cardiac Dysfunction

The only such symptom encountered in this series was pain in the region of the heart. It occurred in 10 per cent of the cases, but was never sharp, being described as a dull oppression over the precordium. Of the ten cases with this symptom, seven had unequivocal electrocardiographic evidence of active carditis, and two others had clinical signs of heart disease. It was associated with a pericardial friction rub only once. On the other hand, 59 per cent in this series had good evidence of cardiac involvement without ever complaining of precordial distress. The absence of this symptom therefore warrants no conclusions, but its presence should suggest, in cases of polyarticular rheumatism the existence of a complicating myocarditis.

D X-Ray Findings

In this series, the teleoroentgenogram showed evidence of cardiac enlargement in only one case. This was of a transient nature and disappeared within seven days. It was not due to pericardial effusion. This patient also complained of precordial pain and in his electrocardiogram a transient partial heart block was discovered. The teleoroentgenogram, in young adults with acute polyarthritis, therefore can not be considered an important adjunct in establishing the diagnosis of rheumatic fever.

EPIDEMIOLOGIC CONSIDERATIONS

1 *Age*—As has been stated, 69 per cent of this series of 100 consecutive admissions with acute polyarthritis showed positive evidence of acute carditis. In this positive group, the ages ranged from eighteen to forty years. Those below the age of thirty predominated, representing 81.2 per cent of the total number. Of those with endocarditis, only four were above, whereas the other thirteen were below the age of thirty. Regarding the incidence of a history of antecedent rheumatic infection, the figures in those above and below the age of thirty are comparable, being 30.8 per cent in the former, and 32.1 per cent in the latter group.

2. *Race*—No cases were discovered in Negroes even though during the period under consideration the hospital population among which this study was conducted constantly received Negro soldiers from a camp near Chicago, whenever any illness requiring hospitalization developed among them.

3 *Familial Incidence*—In this group with acute rheumatic fever, a history of rheumatic fever or of rheumatic heart disease in members of the immediate family was obtained in 32 per cent. In contrast with this incidence, in those with acute polyarthritis without evidence of active carditis a familial history of rheumatic infection occurred in only 1 per cent.

4 *Home Location*—Those cases among this series manifesting evidence of acute rheumatic fever (cf) had lived in various sections of this country prior to their entry into the Army, although the predominant number came from the midwestern states. This is especially interesting inasmuch as all in this group, with almost no exceptions, developed the acute polyarthritis in or within a relatively short distance of Chicago. The frequency distribution among those with active carditis was found to be as

follows 49.3 per cent came from the midwestern states, 23.2 per cent came from the eastern states, 17.4 per cent came from the southern states, and 10.1 per cent came from the far western states.

5 Antecedent Rheumatic Infection—There are striking contrasts between the group with polyarthritis and carditis and those with polyarthritis alone as regards a history of antecedent attacks of rheumatism. In the former group, a positive history was obtained in 40 per cent and in the latter, in 29 per cent. Although this difference hardly seems significant, the importance of antecedent rheumatic infection in the development of an active carditis with a subsequent attack of polyarthritis is emphasized by the fact that of the entire series with acute polyarthritis, 75 per cent of those giving such a history showed evidence of involvement of the heart during the current episode of acute rheumatism. Of those manifesting signs of endocarditis, only 41.1 per cent gave a history of antecedent rheumatic infection.

6 Relation to Antecedent Upper Respiratory Tract Infections—In the present series, considering the cases individually, a history of acute sore throat one to two weeks preceding the appearance of the joint manifestations was obtained in every instance in which the diagnosis of acute rheumatic fever was subsequently confirmed by methods which are described above. However, because the sore throat was usually not severe, the majority of them (87 per cent) did not come to the hospital until the joint symptoms appeared. The exceptions were the 13 per cent who had been admitted because of an acute pharyngitis or acute tonsillitis, the joint pains developing during their convalescence from the respiratory infection.

Analyzing the cases collectively it will be noted (Fig. 29) that the peak incidence of rheumatic fever, plotting the cases according to the onset of the joint symptoms, closely paralleled the peak incidence of acute tonsillitis and pharyngitis in the same hospital population.

7 Relation to Hemolytic Streptococcal Infection—An approximation of the prevalence of hemolytic streptococci in cases of acute tonsillitis and pharyngitis was obtained for the Chicago area, from figures supplied by the University of Chicago, where throat cultures were routinely employed in all cases among the student body who complained of acute sore throat.

Fig 29—Increased frequency of acute rheumatic fever accompanying a rising incidence of hemolytic streptococcal infections For explanation see text.

These figures and their distribution for the first five months of 1943 are shown as percentages in Figure 29 By simple conversion, with the aid of these figures, the monthly incidence of

37.3 per cent had had one or more antecedent attacks of rheumatism, while 62.7 per cent had not. During the current episode of polyarthritis, positive evidence of acute carditis was obtained in 70.6 per cent of those with retained tonsils and in 63 per cent of those whose tonsils had previously been removed. Conversely, of the total number of cases of acute rheumatic fever in this series, 55.4 per cent had retained tonsils, while 44.6 per cent did not. This difference is hardly significant.

9 *Trauma*—In several instances, the patients stated that the first joint to become swollen and painful was one which had been injured a day or two preceding the onset of the arthritis. The significance of this cannot be stated at this time.

10 *Diet*—Inasmuch as all of the patients in this series had been eating the usual nutritious and well-balanced diet provided by the Army mess, lack of any dietary factor would not appear to be of any influence in predisposing these individuals to the acute polyarthritis.

TREATMENT AND PROGNOSIS

Immediately after their admission the patients were started on a regimen of 20 grains of acetylsalicylic acid every four hours. No case appeared to be resistant to acetylsalicylic acid and in no instance was it necessary to resort to amidopyrine or narcotics for relief of pain. No sodium bicarbonate was given with the acetylsalicylic acid and in no instance was there evidence of gastric irritation or rashes due to the drug. Several times daily methyl salicylate was gently rubbed into the involved joints after which they were covered with flannel. A cradle was used when the lower extremities were involved but no external heat was applied. No splints were used and no physiotherapy was necessary. Joint swelling and pain disappeared in a large degree in all cases, within a few hours or, at the most, forty-eight hours after admission.

The diet was the ordinary hospital diet consisting of approximately 3000 calories a day with a normal intake of fluids. This diet was not reinforced with any of the vitamins due to its excellent variety.

There was general nursing care of all cases. Bed rest was compulsory until the patients appeared clinically well and the sedimentation rates and electrocardiograms were normal for three successive weeks. Weekly sedimentation rates and weekly

electrocardiograms were done throughout the period of hospitalization. Neither of these diagnostic procedures was relied upon separately because a significant proportion of the cases showed progressive changes in the electrocardiograms even though the sedimentation rates were normal, and vice versa. For this reason it was deemed advisable to insist on both normal sedimentation rates and normal electrocardiograms for three successive weeks before the patients were allowed out of bed. Once they were allowed out of bed, graduated exercises were given, and in most instances three more weeks of hospitalization were required. Upon discharge from the hospital a convalescent furlough of four weeks was given, provided there was no evidence of endocarditis. Following this furlough the patient was placed on limited service. If there was evidence of endocarditis present in the form of diastolic or significant systolic murmurs, the patient was recommended for an honorable discharge from the Army. The average hospital stay was seventy days.

The hospital is staffed with volunteer workers for supervision of occupational therapy. During convalescence these patients had periods of occupational therapy which stressed the fact that physical activity could be indulged in with no untoward effects. The result was that in no case was psychotherapy necessary because of any form of cardiac neurosis.

In spite of significant electrocardiographic changes in many cases (64 per cent) the clinical recovery and disappearance of these changes was striking in all instances. Of the 64 per cent in whom various transient abnormalities occurred in the electrocardiogram, only 18.7 per cent of this number developed signs of a residual endocardial lesion. No cases developed a pericardial effusion.

Although a thirty-day follow-up examination of all patients discharged from the hospital has failed to show evidence of progressive cardiac damage, re-examinations at a later time are planned in order to establish definitely the fact that healing of the acute myocardial lesions of rheumatic fever can occur without subsequent valvular damage or enlargement of any of the chambers of the heart.

Although the treatment stresses simplicity, the results seem to warrant noting five important factors: (1) Acetylsalicylic acid in sufficient doses will keep the patient comfortable. (2) Bed rest and good nursing care are necessary if there is any evidence of

active infection as shown by clinical examination, sedimentation rate, and the electrocardiogram (3) A well-rounded diet of 3000 calories keeps up the nutrition and makes it unnecessary to add extra vitamins (4) Occupational therapy during convalescence is invaluable to dispel any chance of cardiac neurosis and frustration (5) Protection of the individual patient by a follow-up study and placing him upon limited service should minimize the chances of recurring rheumatic fever This plan allows for a better disposition of those cases remaining in the service

CONCLUSIONS

1 The validity and reliability of the electrocardiograph in establishing the diagnosis of acute carditis among a random group of patients with acute migratory polyarthrititis is demonstrated, provided serial and frequent curves are obtained in each instance.

2 In this study a large variety of nonspecific electrocardiographic abnormalities in the limb leads were noted Their relative incidence and importance are discussed The significance of isolated T wave changes in the precordial lead, indicative of active carditis, is also emphasized

3. Significant electrocardiographic changes were observed in 64 per cent.

4 Because of the high incidence of functional systolic murmurs in young adults, a clear definition of a significant murmur was made Adhering to such criteria, evidence of valvulitis was found in 17 per cent

5 Cardiac enlargement was observed in only one instance

6 The clinical recognition of active carditis is shown to be more dependent on the detection of disturbances in rhythm rather than on murmurs or cardiac enlargement.

7 The difference in the manifestations of acute carditis in children and in the adult is emphasized This fact has an important bearing on the diagnosis of acute rheumatic fever in the armed forces

8 The high incidence of healing of the acute myocardial process in rheumatic fever is demonstrated.

9 A brief discussion of the midsystolic click as it relates to acute rheumatic heart disease is included

10 Confirming previous reports, the influence of heightened vagal tone, relatively or absolutely, in the production of some

of the electrocardiographic changes in acute rheumatic carditis is demonstrated

11 Some of the epidemiological aspects of rheumatic fever are discussed. The relationship of this disease to hemolytic streptococcal infections is emphasized.

12 All correlations are based on a minimal incidence of rheumatic fever in a single hospital population because of rigid objective criteria required by the authors for the diagnosis.

13 Some of the phases in treatment and prognosis are discussed.

SYMPOSIUM ON DISEASES OF THE BLOOD AND BLOOD-FORMING ORGANS

INTRODUCTION RECENT ADVANCES IN THE DIAGNOSIS AND TREATMENT OF BLOOD DISEASES

LEROY H SLOAN, M.D., F.A.C.P.*

It is a great pleasure to write this introductory word to the symposium on diseases of the blood presented herewith by a group of hematologists and clinicians in active daily contact with a large number of patients affected by disease of the blood-forming tissues and blood elements

There has been a steady and rapid progress in recent years both in the recognition of and therapy for such diseases. This progress has been spiked by epochal rises and spectacular peaks such as (1) Minot and Murphy's discovery of the essential element in the therapy of pernicious anemia, (2) the established relation of vitamins C and K to hemorrhagic states, (3) the value of splenectomy in primary thrombopenic purpura and (4) the use of the roentgen ray and irradiated phosphorus in leukemia. Back of such progress there has been a long detailed study of the origin of the normal blood cell, the morphology of diseased cells, the morphology of the cells obtained on bone marrow aspiration and the clinical application of these studies to therapy.

In the Chicago region the study of diseases of the blood has always engaged the attention of able clinicians. B. W. Sippy, whose fame rests largely on his treatment for ulcer, began his work with a study of splenic anemia. J. B. Herrick, eminent cardiologist, was the first hereabouts to describe sickle celled anemia, and Frank Billings gave close observation to the therapy

* Professor of Medicine, University of Illinois College of Medicine, Attending Physician, Cook County Hospital, Head of the Department of Medicine, Illinois Central Hospital

of Hodgkin's disease and leukemia and wrote on the neurological features of pernicious anemia. Williamson of the University of Illinois was at all times deeply concerned with methods for the more accurate determination of the hemoglobin content of the blood as well as in the clinical recognition of blood diseases. Karl Koessler was able to produce in experimental animals an anemia with changes resembling those found in pernicious anemia. This anemia was prevented by adequate vitamin content in the diet. With this nutritional basis he began to treat patients with pernicious anemia with a diet rich in vitamins. Six of his first patients were from my service at the Illinois Central Hospital. These patients all recovered upon a diet high in vitamins, rich in calories and of general character. This diet contained liver. Both Koessler and Minot and Murphy published their results in the same issue of the *Journal of the American Medical Association*. The significance of Koessler's work was lost in the larger significance of the discovery of Minot and Murphy of the curative value of liver. Today we view Koessler's work with greater consideration since the significance of vitamin loss becomes daily more apparent and the important place of vitamins in the therapy of states associated with anemia is recognized.

The discovery of the necessary element in the therapy of pernicious anemia was of prime importance. The elaboration of the technic of preparation, the concentration of the material and the continued efforts of Minot, Murphy, Cohn, Castle, Sturgis and others were, of course, the spur to renewed effort in the therapy not alone of pernicious anemia but also of the other anemias. Relatively soon one found that anemias could be roughly classified therapeutically into those amenable to liver, those requiring only iron for improvement, and those not responsive to either. The concentration of liver extracts, the use of the gastric mucosa, the addition of vitamin B as brewers' yeast—these and many other improvements are an old story.

The criticism of the older hematologists was that they were pure morphologists—that they smeared and looked, reported what they saw, and smeared again. Little by little, hereabouts men turned to the *origin* of the blood cell. During the all-too-short residence of Maximow amongst us, added zeal was well repaid as they followed the clinical significance of his studies and made use of them.

It was probably Richard Jaffe, eminent pathologist and master

teacher, who more than any other brought to this center a clearer knowledge of the origin of normal cells, of the classification of the blood dyscrasias, and of the pathology and prognosis of such diseases. He "popularized the study of the blood dyscrasias" and developed in the younger men under him and in those who came to his brilliant clinics the over-all picture.

The older classification into acute and chronic disease still gives the busy practitioner an instrument for rapid use. In the *acute* disease he expects to find signs and symptoms of a toxemia—fever, apathy, loss in weight, chills, hemorrhages, sweats, progressive weakness, and so forth. This is true in acute leukemia (stem cell, and other varieties), agranulocytosis and thrombocytopenic purpura.

In the *chronic* type he expects to find a slow progress of a relatively benign state with symptoms not necessarily of an anemia. Surprising indeed is the physical strength of some patients with pernicious anemia with counts of only 1,000,000. The patient with florid polycythemia may be disturbed not by his disease but by the questions of his friends, and when he finally develops signs they are in the nervous system and are due to thrombosis in vessels carrying a viscid, packed, slowly moving body of cells.

In pernicious anemia the patient complains of symptoms due to disturbance in the posterior and lateral tracts of his spinal cord—symptoms such as numbness, tingling and paresthesia. And so in the advanced iron deficiencies, in fact in the old chlorotics, the usual constipation and weakness were but a triviality compared to the venous thromboses seen in the retina. The chronic leukemic complains of swollen glands or enlarging abdomen as often or more often than he complains of weakness and loss of weight.

To the busy practitioner the general appearance of the patient is of great help. He recognizes the "cyanotic lividity" which Osler stressed in the patient with *polycythemia* with the chronic conjunctivitis, the overfilled retinal vessels, the bluish red tongue, the soft palate studded with punctate redness, the gingivitis, the varicose veins and the enlarged spleen. The "lemon pallor" of the patient with *pernicious anemia* is perhaps a little less evident in these days because the diagnosis is usually made much earlier and therapy given in adequate amount at an equally early stage. The "limey green" of advanced *chlorosis* is also less obvi-

ous these days when patients are already supersaturated with vitamins of all sorts, but the "waxy smoothness" of the skin of the patient with *leukemia* is still in evidence with his enlarged glands, enlarged spleen, increased metabolic rate, history of loss of weight and retinal sunburst.

The bleeding gums and sore throat do not mean pyorrhea to the physician of today but point to *agranulocytosis* or to *thrombopenia* or perhaps to *scurvy*. The enlarged glands of the neck or the groin or the axilla instantly bring forth the possible diagnosis of one of three major conditions, *leukemia*, Hodgkin's disease or lymphosarcoma, with the less common tuberculous gland still a possibility.

The patient with a blood dyscrasia shows involvement of many tissues of the body. Usually at some stage one finds almost every system and cell involved in one form or another. For example, we have the retinal changes of leukemia, of thrombocytopenia, of hemorrhagic states, the diffuse adenopathy of chronic lymphatic leukemia, the more localized adenopathy of Hodgkin's disease, the enlargement of the spleen in myeloid leukemia and less often in lymphatic leukemia, but also in Hodgkin's disease and in polycythemia, the sclerosing osteitis of Hodgkin's disease, the amyloidosis of the same disease and of the leukemic states, the thromboses of the brain in polycythemia and in leukemia, and the subarachnoid hemorrhage seen in thrombocytopenic purpura—all evidence of the diffuse involvement of the tissues and systems in disease pictures which are seemingly far apart. The study of the patient with a blood dyscrasia today involves a study of the patient himself and numerous examinations of the blood, of the sternal marrow, of the sedimentation rate, the clotting time, the bleeding time, of many smears and still other tests. It is not a study of the blood stream alone but of the whole system, with biopsy of glands where indicated.

The group of clinicians whose views are herewith presented represent those in active charge at our teaching centers. Alt brings the flavor of eastern influence and a large clinic at Northwestern, Davidsohn, a long and distinguished career in hematology, in transfusion reactions, in paternity tests, blood typing and now the Rh factor; Isaacs, the views of his own group at Michael Reese shaded by the previous contact with the group at Michigan, Potter, the experience of an able clinician at Billings engaged in special problems in a new and partially explored

field, Limarzi the teachings of Jaffé, of Williamson and the large and active clinic at Illinois, and Schwartz a large experience at Cook County Hospital where *every* patient is accorded a blood count and the dyscrasias are given special attention

Every day there is an enlarging armamentarium brought to this important field To select the chaff from the oats becomes our problem as clinicians

THROMBOCYTOPENIC PURPURA

LOUIS R. LIMARZI M.D.*

A marked tendency to bleed from the mucous membranes and into the tissues and skin with the formation of petechiae and ecchymoses is a prominent feature of a number of conditions. In some of the hemorrhagic conditions the bleeding tendency is the symptom of a recognized disease, while in another group the bleeding manifestations appear to be the primary feature of the disease.

The mechanism of abnormal bleeding usually involves one or more of the following factors²⁰ (1) quantitative or qualitative changes of the platelets, (2) disturbances in the clotting mechanism, and (3) increased permeability of the capillary wall.

In general, three organs or tissues are primarily concerned in the hemorrhagic disorders. They are the *bone marrow megakaryocytes*, which produce the blood platelets and in turn furnish the thromboplastin, the *liver*, which supplies prothrombin, fibrinogen and heparin, and the *blood vessels* with their endothelial function and capillary reactions. The spleen is a disturbing factor in some thrombocytopenic states and the gastrointestinal tract participates in the mechanism of vitamin K formation and absorption.

A history of any familial or hereditary blood disease in the family, a review of recent contact with drugs, chemicals or physical agents such as x-rays or radium, a thorough search for any dietary deficiency or allergic manifestation to foods, and inquiry as to recent contacts with any active or convalescent disease are important facts to note in attempting to formulate a working diagnosis in purpuric states.²⁰

For the differentiation of the various types of hemorrhagic diseases there are necessary not only a full history, physical

* Assistant Professor of Internal Medicine, University of Illinois College of Medicine, Associate Attending Physician, Department of Medicine, Research and Educational Hospitals, Consultant in Hematology. Research and Educational Hospitals and Henrotin Hospital.

examination and the usual study of the blood, especially of the cellular elements, but in addition (1) an accurate platelet count, (2) bleeding time, (3) coagulation time, (4) retractivity of the blood clot, (5) determination of the prothrombin time as evidence of a deficiency of vitamin K,⁴⁰ (6) determination of the ascorbic acid in the blood as an indication of vitamin C deficiency, (7) the capillary resistance test (Rumpel-Leede) and (8) examination of the sternal bone marrow

Abnormal bleeding is due to many factors. It is therefore imperative to determine the underlying cause of the bleeding process before therapy is instituted. This is especially true in essential (primary) thrombocytopenic purpura, a disease in which splenectomy results in a cure. Many failures from splenectomy in the past in cases diagnosed "purpura hemorrhagica" have occurred because of incorrect diagnosis.

CLASSIFICATION OF THE PURPURAS

Classification of the purpuras is very difficult, because various combinations of many factors may be involved in any one group of cases.³² In all, the changes in the capillary endothelium are probably much more important than the changes in the blood.

CLASSIFICATION OF THROMBOCYTOPENIC PURPURA

(Modified from Wintrobe⁵³ and Rosenthal⁴¹)

- I "Primary" or "essential" purpura haemorrhagica (Verlhof's disease)
 - (a) Thrombocytopenic purpura—acute
 - (b) Thrombocytopenic purpura—chronic
- II Secondary or symptomatic thrombocytopenic purpura
 - 1 Blood diseases
 - (a) Anemias Acute or chronic "primary" or "idiopathic" aplastic anemia, acute or chronic secondary aplastic anemia due to chemicals or physical agents, myelophthisic (tumors such as carcinoma, sarcoma, myelomas, etc., osteosclerosis, etc.), pernicious anemia, erythroblastosis (due to the Rh factor), sickle cell anemia, hemolytic anemia of unknown origin
 - (b) Leukemias Acute stem cell, acute myeloid, lymphatic or monocytic leukemia, late or terminal stages of chronic leukemia
 - (c) Disorders associated with splenomegaly Banti's syndrome, Gaucher's disease, Felty's syndrome, hemolytic icterus (spherocytic jaundice), rarely Hodgkin's disease, thrombophlebitis of portal and splenic veins, "idiopathic" splenomegaly and cirrhosis of liver with secondary splenomegaly
 - 2 Infections (acute and chronic) Septicemia, subacute bacterial endocarditis, typhoid fever, meningococcal sepsis, pneumonia, abscess of the lung, diphtheria, gangrenous pharyngitis, scarlet fever, tuberculosis, syphilis, etc

- 3 Intoxications Quinine, benzol snake venom, pertussis vaccine, mercury bichloride, organic arsenicals, gold salts, sulfonamide drugs, sedormid colchicine,⁴⁴ phenobarbital dinitrophenol ergot, bismuth iodine, organic hair dyes and "leg stocking color"⁴⁵ preparations
 - 4 Radiation Roentgen ray radium
 - 5 Jaundice Hepatitis, cirrhosis of the liver without splenomegaly
 - 6 Chronic nephritis with marked nitrogenous retention, extrarenal azotemia
 - 7 Foods andorris root
- III Congenital thrombocytopenic purpura

LABORATORY PROCEDURES TECHNIC AND INTERPRETATION

The technic of the practical laboratory procedures and their interpretations with relation to thrombocytopenic purpura follow

Bleeding Time (Duke's Method)

A small stab wound is made in the finger or the lobe of the ear and at half-minute intervals the blood is clotted up with a piece of heavy filter paper until bleeding ceases. The cut should be such that the diameter of the first blot is approximately 2 cm. without squeezing. The filter paper should touch the drop of blood which forms and the filter paper should not come in contact with the skin. Normally there are about 6 drops on the filter paper, gradually decreasing in size. Each drop represents the flow of blood in half a minute. The usual normal bleeding time is one to three minutes. The bleeding time determined in this manner does not necessarily express the hemostatic power of every tissue in the body.³¹ Repeated determinations should be made. In purpura haemorrhagica where the blood platelets are reduced the bleeding time is extended from ten to ninety minutes.

Coagulation Time

Coagulation consists mainly in the transformation of fibrinogen into fibrin by means of a ferment called thrombin. The resulting clot is made up of a meshwork of fibrin with the entangled formed elements of the blood. The clear fluid expressed from this clot is the blood serum. There are several methods for the determination of the coagulation time and these vary in their results. Some methods are more simple than others, but less accurate. Howell's method is simple and accurate. With this little stasis as possible 5 cc. of blood is drawn by venipuncture into a dry syringe, which has been washed out with an ether petro-

latum mixture, the ether being allowed to evaporate, and the syringe thus being coated with a thin layer of the oil. The blood is expelled carefully into a clean dry sterile Wassermann tube 21 mm in diameter, care being taken to prevent the formation of air bubbles. The tube is tilted every two to three minutes and when the tube can be inverted without the blood flowing out, coagulation is considered complete. Normal blood coagulates by this method in ten to thirty minutes. In thrombocytopenic purpura the coagulation time is normal, but the clot does not retract or does so only very slowly.

Clot Retraction

Approximately 5 cc of blood is run into a clean dry sterile Wassermann tube and allowed to stand at room temperature without being disturbed. The tube is observed at the end of each hour for six hours and at intervals of six to twelve hours thereafter. Beginning retraction is noticed in normal blood in one to two hours and the clot normally retracts completely within eighteen to twenty-four hours. In a normal blood, after the lapse of eighteen to twenty-four hours, a firm retractile clot is formed which, by virtue of its firm foundation, squeezes out a clear serum that can readily be poured off from the clot. The small firm clot can withstand considerable agitation. In thrombocytopenic purpura there is a delay in retraction, or a failure of the clot to retract due to a decreased number of platelets. The clot is soft and squeezes out only a small amount of serum.

Platelet Count

The blood platelet fluid of Rees and Ecker is used. A small amount of diluting fluid (sodium citrate, 3.8 gm, formalin, 37 per cent reagents, 0.2 cc, brilliant cresyl blue, 0.1 gm, distilled water, 100 cc) is drawn into the bulb of the standardized erythrocyte pipette to moisten the capillary. The blood is then drawn up to 0.5 mark and the pipette diluted to the 101 mark with platelet diluting fluid. After shaking for two minutes, a certified counting chamber with improved Neubauer ruling is filled and allowed to stand for ten minutes. The counting and calculation are done as for a red cell count. The normal platelet count is from 200,000 to 400,000 per cu mm.

The normal life of a blood platelet is about three to five days. The chief function of the blood platelets appears to be their

control over the process of coagulation. Blood platelets are apparently the chief source of prothrombin of the plasma, probable source of at least part of the thromboplastic substance of the tissues and they bring about retraction of the clot. In thrombocytopenic purpura the blood platelets may be totally absent.

Capillary Resistance Test (Rumpel-Leede)

A blood pressure cuff is placed on the upper arm and the pressure maintained just above diastolic pressure for about five minutes. If the test is positive a crop of petechiae (pin-point hemorrhages) appears below the arm band and under it. The petechiae indicate an increased permeability of the capillary endothelium and are usually associated with a decreased number of platelets.

The increase of capillary permeability often associated with thrombocytopenic purpura has not been satisfactorily explained. Macfarlane²³ is of the opinion that the blood platelets, apart from their function as accelerators of coagulation and retraction, apparently have no important part in the production of maintenance of hemostasis. Howell²¹ believes that in the normal individual the continuous disintegration of the circulating blood platelets in the capillaries may cause a localized coagulation of the plasma and that the fibrin formed thereby may serve to protect the integrity of the capillary endothelium. At any rate, it is obvious that before abnormal bleeding can occur there must be a capillary defect.

Sternal Puncture²¹

After the upper portion of the sternum, at the height of the second or third rib, has been prepared in the usual manner, the sternal needle (a modification of the needle devised by Kluma and Rosegger) is forced directly into the bone marrow. One cubic centimeter of sternal marrow is aspirated into a dry syringe and placed immediately into a paraffin-lined tube containing a small amount of powdered heparin as an anticoagulant, the marrow fluid is transferred to a Wintrobe tube and centrifuged five minutes at 2000 r p m, the layers into which the marrow separates (erythrocytes, nucleated cells, plasma, and red and yellow fat) are recorded, the nucleated cell layer (erythroid, myeloid, megakaryocytic tissue, etc.) is mixed with an equal volume of plasma in a paraffin chamber. Counts and films of this nucleated

cell mixture are made. The films are made with an 18-mm. wide cover slip (same thickness as the counting chamber cover slip, but straight edged) The slide is air dried for several hours and stained with May-Grunwald-Giemsa or Wright stain, and studied microscopically for cell distribution and types This procedure has been followed in more than 2375 bone marrow examinations

Maturation of Megakaryocytes Bone Marrow Examination

The only consistent finding in thrombocytopenic purpura is a decrease in the number of circulating thrombocytes (plate-

Fig 30—Normal bone marrow showing an adult megakaryocyte (M)

lets), therefore it is essential both diagnostically and prognostically to examine quantitatively and qualitatively the platelet-forming tissue, the *bone marrow megakaryocytes* (Figs 30-34).

The megakaryocytes are the largest cells in the bone marrow and are readily identified. The cells are classified as "young, adult and degenerated forms" Wright's⁵⁷ original observation that the megakaryocytes are the only source of true platelets has been repeatedly confirmed both clinically and experimentally by many investigators.¹ The earliest type of megakaryo-

Fig 31—Bone marrow in a case of thrombocytopenic purpura showing immature type of megakaryocytic hyperplasia.

cyte (promegakaryocyte) has a number of morphologic characteristics similar to those of the myeloblast. Through a series of changes, first in the nucleus and later in the cytoplasm, the multilobulated adult (mature) megakaryocyte is formed (Fig 30). Megakaryocytes are formed occasionally by a series of complicated mitotic divisions of the nucleus without cell division. In the megakaryocyte the best criteria of maturity are the

amount, character and arrangement of the azurophilic granules in the cytoplasm. The number of lobes or the nuclear configuration is of little value in this respect. Immature megakaryocytes are usually smaller than mature megakaryocytes and contain a deeply basophilic cytoplasm. In degenerating megakaryocytes the giant nucleus shrinks and stains darkly, the cytoplasm dis-

Fig 32—Megakaryocyte showing platelet formation following splenectomy in a case of thrombocytopenic purpura

integrates and the final result is a naked, shrunken nuclear remnant. The formation of platelets occurs by a process of budding or by detachment of portions of the cytoplasm of the megakaryocytes in the bone marrow. It may also occur by cytolysis of the cytoplasm of these cells. The latter process is seen more frequently in aspirated human bone marrow. Mature mega-

karyocytes are formed from the myeloblast through a process of homoplastic hemopoiesis. Thus any disturbance involving the stem cell (myeloblast) will eventually interfere with the normal development of the megakaryocyte and this will result in quantitative and qualitative changes in these cells.

Fig. 33—Megakaryocytes from cases of thrombocytopenic purpura. A, B and D illustrate immature types of megakaryocytes and C is mitosis of a promegakaryocytes, E is an intermediate type of megakaryocytes and F is mitosis in a cell of the same type as E.

In essential thrombocytopenic purpura, in spite of the marked decrease in the number of platelets in the peripheral blood, a marked megakaryocytic hyperplasia is demonstrated in the bone marrow.^{11 28 46} Young forms of megakaryocytes with single nuclei and relatively little or only moderately abundant cytoplasm and relatively few azurophilic granules are frequently

Fig 34—A, Hyaline megakaryocyte with azure-free cytoplasm in the bone marrow in a case of thrombocytopenic purpura B, Intermediate type of megakaryocyte showing extrusion of the nucleus in a case of thrombocytopenic purpura C, Toxic megakaryocyte in a case of thrombocytopenic purpura due to gold salts for the treatment of arthritis D, Degenerated megakaryocyte from normal bone marrow. E, Multipolar mitosis of a normal adult megakaryocyte F, Normal adult megakaryocyte showing the characteristic multilobulated nucleus and granular azurophilic cytoplasm

observed in the acute phase and to a less extent in the chronic phase of purpura haemorrhagica (Fig 31) Pathologic or "toxic" forms of megakaryocytes (Fig 34) such as lack of normal azuro-

philic granules,⁴⁸ vacuolization of the cytoplasm, small or large megakaryocytes with degenerative types of nuclei⁵² and a hyaline cytoplasm and an absence of azurophilic granules are frequently observed in purpura haemorrhagica and in secondary thrombocytopenic purpura haemorrhagica—nephritis, gold salts, aplastic anemia, sulfonamide drugs, and so forth

Morphologic Changes in Platelets

Normally, platelets vary from 2 to 4 μ in diameter. They are spheric or ovoid granular bodies. When stained by Wright's stain, azure granules are seen in a hyaline, light blue cytoplasm. In the ordinary blood film they are seen isolated or clumped together. In thrombocytopenic purpura haemorrhagica, bizarre and pathologic forms of platelets and pseudoplatelets are observed in the peripheral blood. The latter forms are derived from the pathologic hyaline megakaryocytes in the bone marrow. Morphological changes are seen in the platelets such as giant forms, minute platelets and deeply stained ones. Rarely portions of the bone marrow megakaryocytes are seen in the peripheral blood.

ESSENTIAL THROMBOCYTOPENIC PURPURA (WERLHOF'S DISEASE⁵³)

Purpura haemorrhagica is a condition of unknown etiology which is characterized clinically by spontaneous bleeding in the form of petechiae or ecchymoses into the skin, as well as hemorrhage from the mucous membranes and into the various organs. Petechiae are usually scattered over the arms, abdomen and legs and bleeding may occur from the nose, gums, and in some cases from the bowel, kidney and vagina. Intracranial hemorrhage is the most serious complication and may involve the brain, the spinal cord or the cerebrospinal meninges. Retinal hemorrhage is not unusual. In females there are usually disturbances in the menstrual cycle.

The first symptom of purpura haemorrhagica may be manifested by localized bleeding from the nose (epistaxis), bleeding gums, bleeding from the genito-urinary tract, profuse menstruation or menorrhagia or bleeding into the gastro-intestinal tract. Sooner or later purpuric lesions of the skin appear. These are minute, red hemorrhages which range in size from that of a pin point to that of a pinhead or slightly larger. Ecchymoses, large purple areas and even hematomas may occur.

Purpura haemorrhagica is a disease of childhood and young adults. It occurs more frequently in females than males. It is uncommon among Negroes. The disease has been reported during the first year of life and may even be present at birth in full-term and premature infants. A congenital type of the disease has been described. In 70 per cent of the author's series of forty-three cases the disease appeared before the age of twenty-four. The youngest patient was a female infant thirteen months of age and the oldest was a woman of fifty-five years. There were twenty-five females and eighteen males. The disease was observed in three female Negroes.

Pathogenesis

The cause of essential thrombocytopenic purpura is not entirely clear. Much clinical and experimental work has been done and many theories have been advanced. No single theory for the cause of the disease adequately accounts for all the known facts relating to the disease. Frank¹⁵ was of the opinion that the reduction in the number of circulating blood platelets and the morphologic changes of the megakaryocytes in the bone marrow was due to some noxa probably having its origin in the spleen. Minot³⁵ believes that the causative agent acts on the blood platelets, on the megakaryocytes or on the bone marrow as a whole. Kaznelson,²⁶ who first removed the spleen in a case of essential thrombocytopenic purpura, believed that the thrombocyte reduction in the peripheral blood was brought about by an increased thrombolytic activity of the spleen. The increase in the number of megakaryocytes in the bone marrow, in his opinion, was compensatory hyperplasia.²⁵

Brill and Rosenthal⁴ stated that the disease was associated with a disturbance in function of the capillary wall in addition to a disorder of the blood platelets. The changes in the capillary wall, they thought, were probably due to a reduction in the number of blood platelets. Wiseman, Doan and Wilson⁵⁶ support the theory of splenic cytolysis as the cause of the thrombocytopenia in this disease. Our studies²⁸ and those of others¹⁴ support the view that the disease is due to a faulty maturation of the megakaryocytes in the bone marrow. Splenectomy removes a factor which is inhibitory to maturation. Some investigators attribute the megakaryocytic hyperplasia to the factor of bleeding, which is dependent on the severity of the disease.²³

The function of the spleen in its relation to essential thrombocytopenic purpura is not definitely understood. It is usually regarded as the graveyard of both erythrocytes and thrombocytes. On the other hand, the depression of the megakaryocytes in the bone marrow was believed by Frank¹⁶ to be due to some inhibitory splenic influence directed against the reticulo endothelial system from which the platelet-forming cells and granulocytes have their origin. Troland and Lee⁵⁰ report that extracts of spleens removed from patients with thrombocytopenic purpura contain a substance ("thrombocytopen") which, when injected into experimental animals will depress the blood platelets to a low level. Many investigators have failed to substantiate this work. Paul²⁸ studied the effect of intravenous injections of acetone splenic extracts from cases of essential thrombocytopenic purpura on the platelets and hemopoietic organs of rabbits. He noticed a transient significant depression of the platelet count in the peripheral blood of the rabbits, but there was no effect upon the number or cell structure of the megakaryocytes in the bone marrow. The spleen, liver and lungs of the rabbits showed no distinctive pathologic changes.

Pathology

Except for the widespread hemorrhage, both gross and microscopic, which is a constant feature found in this disease at autopsy, and the finding of a megakaryocytic hyperplasia of the bone marrow there is little else of pathologic significance in thrombocytopenic purpura that is observed at necropsy. Studies on the spleens removed surgically, except for an occasional megakaryocyte, have failed to reveal any significant gross or histological abnormalities that would add any light to etiology of thrombocytopenic purpura.

Clinical Manifestations

The symptoms and physical findings are variable because the disease may occur in both acute and chronic forms and further because of the tendency to relapses and remissions. The patients are more often observed during the relapse phase. A family history of ready bruising, frequent nosebleeds, profuse flow and irregularities in menstruation, excessive bleeding following small cuts or the extraction of a tooth, tonsillectomy and other operations or injuries are by no means unusual in these cases. The lymph nodes are not enlarged and the spleen is slightly palpable in less than one third of the cases. Large or massive spleens are

not observed in true cases of purpura haemorrhagica. In the chronic cases the condition of the patient is good.

In acute cases or during chronic phases of the disease with excessive bleeding the patient is pale because of the anemia. There may be a slight fever and a rapid pulse. Examination of the body may reveal a generalized distribution of petechiae and ecchymoses. The petechiae do not change on pressure. The hemorrhage areas vary from a dull red to yellow, purple and blue in color depending on their age. The signs and symptoms of hemiplegia or meningitis appear when intracranial hemorrhage takes place.

Hematology

The characteristic blood finding is thrombocytopenia. The *platelets* are markedly reduced in number or even absent from the peripheral blood. In chronic cases the platelet count usually varies between 75,000 to 100,000 per cu. mm. although counts as low as 60,000 per cu. mm. are observed without obvious signs of bleeding. Sooner or later cases with such low platelet counts will present bleeding into the skin, either spontaneous or following the application of a tourniquet to the arm in order to obtain blood from a vein. The tourniquet test is strongly positive in practically all the case during the active phase of the disease. During remission the test is often negative. Rarely may the platelet count be less than 50,000 per cu. mm. and the tourniquet is negative. If the skin over the vein is "flicked with the finger" while the tourniquet is still applied to the arm a crop of minute petechiae will gradually make their appearance. Usually bleeding does not occur unless the blood platelets are fewer than 60,000 per cu. mm. The chamber platelet count should always be checked with a blood smear that has been properly prepared and stained with Wright's stain. The blood platelets, besides being low, show morphological changes such as marked variation in size and abnormalities in shape.

The *bleeding time* is prolonged and the coagulation time is normal with a poor or absent clot retraction.

Anemia, if present, is usually normocytic in type. Severe and continued bleeding usually results in a microcytic hypochromic anemia. When bleeding has been excessive with erythrocyte counts as low as 1 to 1.5 million per cu. mm., the anemia is often macrocytic in type. Nucleated red cells are frequently

observed in the peripheral blood. Depending on the amount of bleeding a moderate to marked reticulocytosis is usually present.

The *leukocyte count* is usually normal. In cases with severe hemorrhage the count may be moderately elevated. Leukocyte counts as high as 20,000 with a moderate "shift to the left" to include an occasional neutrophilic myelocyte and metamyelocyte may occur. Leukopenia with a relative lymphocytosis in chronic cases has been described.⁴⁰ With secondary infections or following blood transfusions or where absorption products from suffusion or hematomas occur the polymorphonuclear neutrophils show varying degrees of "toxic" granulations in the cytoplasm.

The urine and stools may contain gross or occult blood. The blood calcium and fibrinogen and prothrombin time and cevitamic acid level of the blood are all within normal limits.

The *bone marrow examination* is the most important single differential diagnostic procedure. Symptomatic or secondary thrombocytopenic purpura such as occurs in leukemia, aplastic anemia, myeloma, leukosarcoma, pernicious anemia, Gaucher's disease, and "toxic" states are readily diagnosed and immediately separated from essential thrombocytopenic purpura. In acute thrombocytopenic purpura the bone marrow reveals a uniform stimulation with a myeloid, erythroid and *megakaryocytic hyperplasia*. In the more chronic cases without significant hemorrhage, the myeloid and erythroid hyperplasia may be absent, but the megakaryocytic hyperplasia persists. In the acute phase of the disease many of the megakaryocytes are of the young form and in the less acute and chronic phase of the disease most of the megakaryocytes are adult in type with an abundance of azurophilic granules in the cytoplasm. Some of the megakaryocytes reveal morphologic changes such as a hyaline cytoplasm and an absence of azurophilic granules. Degenerated or toxic forms of megakaryocytes with vacuolization of the cytoplasm are occasionally seen in primary purpura hemorrhagica, but are more frequently observed in greater numbers in some of the cases of symptomatic purpura hemorrhagica especially following infections and intoxications.

Following splenectomy the megakaryocytes qualitatively revert to normal, but quantitatively a moderate megakaryocytic, as well as myeloid and erythroid hyperplasia persists.

In my series of forty-three cases of thrombocytopenic pur-

pura a megakaryocytic hyperplasia was observed in forty. In two cases with an aplasia of the megakaryocytes one patient died following cerebral hemorrhage and the second died following splenectomy (Case VI). In a third case with a marked decrease in the number of bone marrow megakaryocytes, recovery occurred following a stormy postoperative course (Case VII).

TREATMENT

Medical Treatment

Untreated, the disease is often characterized by a cycle course of remissions and exacerbations. Temporary or apparent cures supposedly brought about through medical treatment, therefore, should be appraised with this fact in mind. In children less than ten years of age and in older individuals over forty years of age, thrombocytopenic purpura is usually mild in character and a spontaneous remission or one induced by medical treatment is usually complete and permanent. Only rarely is splenectomy indicated. Some investigators believe that the thrombocytopenic purpura of early infancy and childhood and that of adolescence and adult life are fundamentally different conditions. Clinically and hematologically there is little to support such a theory.

General treatment should include rest in bed, good nursing, and an appropriate diet. In general the diet should be liberal in animal proteins, fruits and green vegetables. Foods known for their value in furnishing hemoglobin-building materials, and for their vitamin content such as liver, chicken gizzard, kidney, eggs, apples, apricots, peaches, prunes, fresh lima beans, shredded wheat and puffed wheat, should be given in liberal amounts. For the anemia the administration of iron is indicated, such as ferrous sulfate 1 gm daily, reduced iron 3 gm daily or iron and ammonium citrate 6 gm daily. Preparations containing both iron and liver extract usually accelerate the rate of recovery.

Although *vitamin therapy* is not specific in thrombocytopenic purpura, since there is no evidence that lack of any of the synthesized vitamins including ascorbic acid is the cause of the disease, small amounts of some recognized multiple-vitamin preparation should be administered until the patient has recovered from the bleeding episode.

The *elimination from the diet* of foods to which the patient is allergic or sensitive has been suggested by the work of Squire and Madison.⁴⁷ According to these investigators, when patients

with thrombocytopenic purpura were placed on elimination diet the blood platelets returned to normal levels

The *removal of offending drugs* such as quinine, arsphenamine, benzene and sedormid which can act directly on the bone marrow megakaryocytes or cause depletion of the circulating blood platelets is an important precautionary measure, although these drugs are not the primary cause of thrombocytopenic purpura

During the phase of remission, *foci of infection* should be removed

Snake venom has been used both as a measure for controlling the bleeding and as a prognostic test For treatment from 0.4 to 1 cc and occasionally 2 cc of moccasin venom is given subcutaneously twice weekly Marked local reactions in the form of induced ecchymoses may occur Clinical improvement occurs without any definite improvement in the blood platelet level For the prognostic venom reaction, 0.1 to 0.2 cc. is injected intradermally A positive intracutaneous reaction occurs in practically all cases of purpura before venom treatment is started This intracutaneous reaction may persist in some cases but in other cases there may be a reversal from a positive to a negative reaction This persistence or reversal is said to be of value in determining the trend of the purpuric state According to Peck, Rosenthal and Erf,³⁹ patients treated with snake venom without reversal of the positive skin test to a negative one are likely to obtain little benefit from splenectomy We have had no experience with this test

There are a large group of *miscellaneous measures* and various remedies⁵⁴⁻⁵⁶ which are of unproved value in the treatment of thrombocytopenic purpura The tendency for spontaneous improvement in this disease makes it difficult to evaluate their merits They include injections of foreign proteins, calcium, proprietary coagulants, epinephrine hydrochloride, viosterol, large doses of cevitamic acid, and other vitamins such as K, B₂ and A, liver extract, ventriculum, sesame oil, progynon, sulfuric acid, ergot, turpentine, anterior lobe of the pituitary, parathyroid extract, iodine and coal tar, snake venoms (tiger, moccasin) and antivenins (Bothrops), kephine hydrochloride, fat-soluble "T" factor and high protein diet.

Recently citrus pectin,²² in the form of powder taken by mouth (capsules) in doses of 1 gm three times a day, one-half

to one hour before meals, has been reported to cause a cessation of bleeding without affecting the platelet level in cases of idiopathic thrombocytopenic purpura.

Foley has been able to induce remissions in two cases of thrombocytopenic purpura with marked vaginal bleeding as a prominent part of the hemorrhagic syndrome by the oral administration of stilbestrol in 5-mg doses every four to six hours for a period of two to three days

High voltage roentgen ray over the spleen or the exposure of patients with thrombocytopenic purpura to ultraviolet rays are of no definite therapeutic value

Blood Transfusions

Where there has been much bleeding, blood transfusions are immediately indicated. The transfusions are repeated as often as necessary. Transfusions supply lost plasma volume and red blood cells, and the presence of platelets is useful in controlling the bleeding. Citrated blood given by the indirect technic is as effective as direct transfusions of whole blood in controlling excessive bleeding. The transfused blood platelets have little or no effect in reestablishing the normal blood platelet level and therefore should not be regarded as a curative measure. The blood transfusions serve to carry the patient along until a spontaneous remission sets in or as a preoperative measure in removal of the spleen.

Blood in amounts of 500 cc in the case of adult patients and in doses of 200 cc to 300 cc in the case of children should be given rather than several small transfusions. Injections of whole blood intramuscularly are not of any practical value. In cases of severe anemia due to marked loss of red blood cells, the use of concentrated red cell suspension (erythrocyte concentrates) will aid in restoring the normal circulating red cell volume. Rarely, intrasternal blood transfusions may be the only avenue of administration.

Surgical Treatment

Splenectomy apparently results in a complete cure. Total cessation of bleeding in thrombocytopenic purpura in most cases occurs as soon as the splenic pedicle has been tied and before the platelets show any appreciable rise in the peripheral blood. Within twenty-four to forty-eight hours after splenectomy the

blood platelets reach a normal level (Fig 32) and in many instances the platelet level after several days may reach values of 500,000 per cu mm or more I have observed one case in which the blood platelets following splenectomy reached a peak of 1,200,000 per cu mm in ten days Eventually the blood platelets return to a normal level In twenty cases of thrombocytopenic purpura observed by me following splenectomy the blood platelets promptly reached a normal level In no instance was there a later fall to the original low levels of 50,000 or less and there was no reappearance of the bleeding diathesis

Failures following splenectomy in some cases diagnosed thrombocytopenic purpura may be attributed to a number of factors (1) incorrect diagnosis, (2) neglect of several important features before splenectomy is begun, such as the stage of the disease (acute or chronic phase) and the preoperative treatment, (3) the presence of accessory spleens,⁵⁶ (4) the postoperative treatment, and (5) the failure to examine the sternal marrow in order to determine the quantitative and qualitative status of the platelet-forming tissue, the megakaryocytes

Splenectomy is of no value in symptomatic thrombocytopenic purpura Splenectomy done in acute leukemia and aplastic anemia because of the bleeding tendency associated with a thrombocytopenia has been accompanied by disastrous results

The operation should be performed by a skillful operator Warren H Cole in a late number of the *Surgical Clinics of North America*⁶ has considered in detail the technic of splenectomy Since splenectomy in acute phases carries a very serious risk,⁵⁴ energetic action is demanded to bring about a temporary remission through the liberal use of blood transfusions before the operation is begun Not infrequently it will appear obvious, however, that cases of the acute incipient type, as well as the acute exacerbation of the chronic type, will result in a fatality unless splenectomy is performed Death will result from external hemorrhage or from a sudden fatal termination through cerebral hemorrhage If it appears that therapy has been ineffective, an emergency operation is indicated

The care of the patient after operation has the same importance in the final outcome as preoperative therapy The most important item in postoperative therapy is the administration of blood as transfusions and the transfusions are continued after splenectomy until the blood proteins and erythrocytes approach

normal or are appreciably raised. In general, all patients with anemia should have at least one transfusion postoperatively. In patients with severe anemia it may be necessary to give six or seven transfusions in as many days. This procedure will shorten the convalescence tremendously, and will minimize the amount of complications. Frequently, splenectomy is followed by an unexplained fever and tachycardia about twenty-four hours after operation. Cole believes that it is associated with a disturbance in the fluid and electrolytic balance, particularly the former. Treatment consists in an adjustment of the fluid intake, especially intravenous glucose and mineral electrolytes. The patients, following splenectomy, should be watched closely for hemorrhage from the splenic pedicle and for the early complications of pneumonia and atelectasis. Occasionally abdominal distention becomes very prominent. Less frequently an infection of the wound may develop. Symptomatic treatment of all complaints or complications and attention to minor details may be sufficient to alter the course from fatality to recovery.

The presence or absence of an adequate number of megakaryocytes in the bone marrow will decide between a good or poor result following splenectomy. Obviously a marked decrease or absence of platelet-forming cells (megakaryocytes) in the bone marrow contraindicates splenectomy. Many of the supposed failures with lack of platelet rise and the continuation of the abnormal tendency to bleed following splenectomy in thrombocytopenic purpura can be attributed to a failure to appreciate the diagnostic and prognostic value of bone marrow studies. In only two of the twenty-two cases of thrombocytopenic purpura subjected to splenectomy did the operation fail to bring about a normal platelet level in the peripheral blood, and a complete freedom from all the bleeding tendency (Cases VI and VII).

Illustrative Cases

The following cases illustrate several of the more important features of thrombocytopenic purpura and the effect following the removal of the spleen.

CASE I—Essential Thrombocytopenic Purpura in a Boy—P. H., a white boy, aged fifteen years, was admitted to the Illinois Research and Educational Hospitals on September 12, 1939, complain-

ing of epistaxis. Bleeding from the nose was first experienced in June, 1939, and was followed in a short time by persistent oozing of blood from the gums. Physical examination was essentially negative, except for numerous petechiae over the posterior aspect of the neck, cubital region, and chest. The spleen was not palpable. Blood studies on entrance showed platelets 40,000, erythrocytes 4,490,000, hemoglobin 13.0 gm., and a definite megakaryocytic increase of the sternal bone marrow. The bleeding time was twenty minutes and the coagulation time was nine minutes. The tourniquet test was positive. There was no clot retraction at the end of twenty-four hours.

The patient remained in the hospital under observation for several months. During this time he had many severe attacks of epistaxis. Platelet counts as low as 11,000 were obtained. Splenectomy was performed on December 21, 1939. The spleen weighed 290 gm. Six hours after removal of the spleen the platelets numbered 76,000, and eight days postoperatively a count of 980,000 was obtained. Several months later the blood platelets returned to a normal level. Bleeding subsided completely following splenectomy, and has continued so up to the present time.

CASE II—Essential Thrombocytopenic Purpura in a Young Girl—
D. T., a white girl, aged fourteen years, was admitted to the Illinois Research and Educational Hospitals on March 10, 1938, complaining of frequent attacks of epistaxis and excessive menstrual bleeding. Bleeding from the nose was first noticed in October, 1937, at which time she experienced a nosebleed which persisted for two days. Menstrual period in November, 1937, continued for nine days, and in December, for fourteen days.

Physical examination was essentially negative, except for numerous petechiae, especially over both lower extremities. The spleen was not palpable. Blood studies on entrance showed platelets 48,000, erythrocytes 3,680,000, hemoglobin 8.5 gm., and a definite megakaryocytic increase of the sternal bone marrow. On March 19 the bleeding time was three minutes and the coagulation time was ten minutes. There was no clot retraction at the end of twenty-four hours and the tourniquet test was positive. Blood studies on March 25 showed platelets 61,000, erythrocytes, 2,930,000, hemoglobin 7.25 gm., and megakaryocytic hyperplasia of the sternal bone marrow.

Splenectomy was performed on April 11, 1938. The spleen weighed 157 gm. Twenty-four hours after operation the platelet count was 72,000. The platelets increased progressively, and on April 18 (seven days after splenectomy) they numbered 386,000. Following splenectomy there has been no bleeding at any time.

Thrombocytopenic purpura may be associated with various diseases such as hyperthyroidism,¹² catarrhal jaundice¹ and pulmonary tuberculosis. The association represents the incidence of two unrelated conditions. The same is true regarding the occurrence of purpura haemorrhagica in association with pregnancy.⁴⁸

The following cases of thrombocytopenic purpura associated with pregnancy, hyperthyroidism and pulmonary tuberculosis illustrate the important features, course and treatment of two unrelated disorders occurring in the same patient.

CASE III—Essential Thrombocytopenic Purpura Associated with Pregnancy—B P, a white girl aged seventeen years, was admitted to the Illinois Research and Educational Hospitals on July 26, 1940. She had severe epistaxis, bleeding gums, purpuric spots, and bruised easily since December, 1938. At the time of entrance she was pregnant approximately seven months. Physical examination revealed red, spongy gums. The liver was palpable and tip of the spleen could be felt. The bleeding was controlled by blood transfusions and the patient was allowed to go into labor spontaneously on September 29, 1940. She delivered a normal full term baby girl that weighed approximately 6½ pounds. The puerperium was afebrile and uneventful.

Blood studies on her second admittance to the hospital showed platelets 100,000, erythrocytes 3,120,000, hemoglobin 9.8 gm., and a myeloid, erythroid and megakaryocytic hyperplasia of the sternal bone marrow. The bleeding time was twelve minutes, the coagulation time was nine minutes, and the beginning clot retraction occurred at the end of one and one-half hours. She was prepared for splenectomy by the administration of blood, and on October 23, 1940, the spleen was removed. The spleen weighed 203 gm. Twenty-three days postoperatively, blood studies revealed platelets 200,000, erythrocytes 5,910,000, and hemoglobin 17.5 gm. Since splenectomy there has been no bleeding from the nose or gums.

CASE IV—Essential Thrombocytopenic Purpura Associated with Hyperthyroidism—R V, a white woman aged twenty-two years, admitted to the Illinois Research and Educational Hospitals on June 24, 1938, had frequent attacks of epistaxis. Nasal hemorrhages commenced about February 15, 1938, and usually persisted for about one-half hour. She continued to have two or three hemorrhages weekly up until June 1, when the attacks became more frequent and prolonged. Menstrual history was normal until June

THROMBOCYTOPENIC PURPURA

12, 1938, and continued until July 1, with a marked increase in the bleeding

Physical examination revealed a moderate pallor of the skin and numerous bright red petechiae over chest, abdomen, back and extremities. The spleen was palpable and the tourniquet test was strongly positive. She also presented the symptoms and findings of exophthalmic goiter, including nervousness, irritability, tremor, palpitation, moderate weight loss and heat intolerance. The thyroid gland was bilaterally enlarged and soft in consistency. Exophthalmos was conspicuous. The basal metabolic rate was plus 33 per cent and the blood cholesterol was 143 mg per 100 cc. of blood.

Blood studies on entrance showed platelets 23,000, erythrocytes 2,300,000, hemoglobin 6.3 gm., and marked increase of the megakaryocytes on sternal bone marrow examination. The coagulation time was five minutes and the bleeding time was eight minutes. There was no clot retraction at the end of twenty-four hours.

Splenectomy was performed on June 30. The spleen weighed 270 gm. Five hours postoperatively there were 136,000 platelets with many large forms. Twenty-four hours after splenectomy platelets numbered 185,000, and on June 11 (eleven days after surgery) the platelet count was 473,000.

The patient was discharged from the hospital on July 24, with symptoms and signs due to bleeding disorder entirely cleared up, but the thyroid disease persisted.

She was again admitted to the hospital on November 11, 1938 with no change in the thyroid disorder. Blood studies at this time showed platelets 265,000, erythrocytes 4,150,000, and hemoglobin 11.5 gm. She was entirely cured of her thrombocytopenic purpura. She was prepared for surgery and a subtotal thyroidectomy was done on November 26. The postoperative course was uneventful and she left the hospital on December 1, 1938 in apparently good condition.

CASE V—Essential Thrombocytopenic Purpura Associated with Pulmonary Tuberculosis—E. L., a white boy aged thirteen years first entered the Illinois Research and Educational Hospitals on December 1, 1942, complaining of frequent and persistent attacks of epistaxis and bleeding from the gums. His mother stated that the boy had had nosebleeds since he was six weeks old. At first the nasal bleeding was slight and occurred once a month but the bleeding has gradually become more severe until the present time when it occurs at intervals of two weeks. He complained of a cough for the last two weeks.

Physical examination, except for a few dry, "squeaking" rales over the left lung anteriorly near the 2nd and 3rd ribs, was nega-

tive The spleen was not palpable, and the tourniquet test was negative Blood studies on entrance showed a platelet count of 20,000, erythrocytes 3,210,000, hemoglobin 60 gm, leukocytes 7100 with polymorphonuclear neutrophils 72 per cent, lymphocytes 21 per cent and monocytes 7 per cent The sedimentation rate of the erythrocytes (Wintrobe tube) was 33 mm in one hour The sternal bone marrow revealed a marked megakaryocytic, myeloid, and erythroid hyperplasia The bleeding time was eight minutes and the coagulation time was twenty-one minutes with no clot retraction at the end of thirty hours Roentgen examination of the lungs suggested bronchiectasis Several sputum specimens on examination revealed many acid-fast bacilli and the stomach washings also showed tubercle bacilli

Conservative treatment, including local treatment to nose and frequent blood transfusions, failed to stop the nasal bleeding which became more frequent and exhausting to the boy Splenectomy was finally performed on January 1, 1943 Five small accessory spleens were found, all of which were removed They were located in the pedicle, some of them lying against the pancreas The spleen weighed 310 gms Nasal bleeding stopped immediately following splenectomy, and he was given a number of blood transfusions postoperatively Blood studies on January 19, 1943, before his transfer to a tuberculosis institution, showed a platelet count of 460,000, erythrocytes 5,480,000, hemoglobin 160 gm, and leukocytes 14,100 The bone marrow revealed a moderate megakaryocytic hyperplasia

The finding of megakaryocytic hyperplasia in the bone marrow in thrombocytopenic purpura is essential before splenectomy In our experience an excellent result has followed splenectomy in all cases with a hyperplasia of the megakaryocytes In another group of acute and chronic thrombocytopenic purpuras a hypoplasia or aplasia of the megakaryocytes is observed Failure of improvement after splenectomy can be definitely correlated with the marked diminution or depletion of the megakaryocytes in the bone marrow

The following cases illustrate the course of events that may result when splenectomy is undertaken in a patient with aplasia of the megakaryocytes and in another instance where there is a marked diminution of megakaryocytes in the bone marrow

CASE VI—*Chronic Thrombocytopenic Purpura with Aplasia of the Bone Marrow Megakaryocytes**—D C, a white woman aged

* This case was observed and studied with Doctor Albert VanderKloot, Chicago

thirty-three years, first entered the Illinois Research and Educational Hospitals on December 20, 1942, with generalized bleeding from the nose, gums, bladder, rectum, and into the skin and mucous membranes. She was in good health about four years ago when she had a miscarriage, following which she continued to have massive uterine hemorrhages which continued in spite of curettage and uterine packing. With the aid of numerous transfusions the bleeding subsided. She had had numerous subcutaneous hemorrhages following very minor blows or accidents for some months before this, but no particular attention was paid to them. For the past three years she had had a series of relapses with bleeding from the nose, gums, rectum and into the skin. The platelet count had been as low as 10,000, the erythrocytes decreased as low as 1,000,000, with a hemoglobin value of 16 per cent. She had been treated with iron, liver, blood transfusions, endocrine preparations, snake venom, calcium, pectin and large doses of vitamin C, following which there appeared to be temporary, but never a complete remission of the purpuric condition.

Physical examination revealed numerous and generalized petechiae distributed over the face, neck, chest, abdomen and both upper and lower extremities. There was profuse bleeding from the nose, gums and nasopharynx. Retinal hemorrhages were observed on examination of the eyegrounds. A hemorrhagic ulceration of the throat caused difficulty in swallowing. The spleen was not palpable and the tourniquet test was markedly positive. The bleeding times were over twenty minutes and the coagulation was ten minutes. There was no retraction of the clot at the end of thirty-six hours.

Blood studies on entrance showed a platelet count of 10,000, erythrocytes 2,680,000, hemoglobin 7.25 gm., leukocytes 3800 with polymorphonuclear neutrophils 42 per cent (many contained "toxic" granulations in the cytoplasm), lymphocytes 52 per cent, eosinophils 2 per cent and monocytes 4 per cent. No platelets were seen on blood smear examination. Repeated bone marrow examinations revealed a marked myeloid-erythroid hyperplasia with a markedly reduced number of megakaryocytes, almost a complete aplasia of these elements.

Splenectomy was performed on December 22, 1942. The spleen weighed 70 gm. Bleeding did not stop after removal of the spleen and marked bleeding from the bladder started shortly after the operation. Although she was given many blood transfusions she died of a cerebral hemorrhage on the twelfth day postoperatively. The blood platelets at no time reached a level of over 10,000 following splenectomy.

CASE VII—*Thrombocytopenic Purpura with a Marked Diminution of the Megakaryocytes in the Bone Marrow A Case of So-called "Uterine Thrombocytopenic Purpura."*—A E, a white woman aged twenty-two years, entered the Illinois Research and Educational Hospitals for the first time on March 10, 1940, complaining of profuse and continuous vaginal bleeding for the past eight weeks. She had received seventeen blood transfusions of 500 cc each before she entered the hospital. She was in good health until about two months ago, when she first began to have frequent attacks of epistaxis and bruised easily. The menstrual periods were very profuse and continued for six to seven days.

Physical examination on entrance into the hospital revealed a very pale individual with purpuric and ecchymotic areas on both arms, especially the right, and on the left thigh. There were petechial hemorrhages on the mucous membrane of the mouth, pharynx and buccal mucosa. Vaginal bleeding required change in her vaginal pad every two hours. The spleen was palpable two to three fingerbreadths below the left costal margin on deep inspiration. The tourniquet test was markedly positive. The bleeding time was ten minutes and the coagulation time was four minutes. There was no retraction of the clot at the end of twenty hours.

Blood studies on admittance showed a platelet count of 40,000, erythrocytes 1,118,000, hemoglobin 3.4 gm, leukocytes 16,450 with myeloid immaturity, reticulocytes 57 per cent, icterus index 3 units, and the mean corpuscular volume was 101 cubic microns. The bone marrow revealed a marked erythroid and myeloid hyperplasia with a marked diminution in the number of megakaryocytes.

Emergency splenectomy was performed on March 10 (late afternoon on day of admittance to hospital). The spleen weighed 415 gm, and a small accessory spleen near the splenic pedicle weighed 5 gm. The blood platelets gradually increased to 160,000 seven days after the operation. This was followed by a progressive drop in the platelets until they reached a level of 30,000 on April 18, 1940.

The vaginal bleeding continued and was exhausting to the patient in spite of frequent blood transfusions. On April 28, a series of roentgen ray treatments over the ovaries was begun. The vaginal bleeding gradually decreased in amount and finally stopped permanently. On August 16, 1940, the platelets numbered 80,000, erythrocytes 4,720,000, leukocytes 10,850 with a myeloid immaturity, reticulocytes 1 per cent and icterus index 7.5 units. The bleeding time was ten minutes and the coagulation time was nine minutes. There was a soft retractile clot at the end of twenty-four hours. The tourniquet test was still positive. The bone marrow

showed a myeloid and erythroid hyperplasia and definite increase in the number of normal appearing megakaryocytes.

The patient received approximately ninety-three blood transfusions of approximately 500 cc each while she was in the hospital. The blood studies October 23, 1940, showed blood platelets 210 000, erythrocytes 4,480,000, hemoglobin 12.25 gm and leukocytes 9650 with a normal differential count. The bleeding time and coagulation time were normal and the retraction of the clot occurred in two hours. The tourniquet test was negative. Bone marrow studies revealed many mature forms of megakaryocytes. She was free of the bleeding tendency. Except for a few symptoms due to the induced menopause, she has felt fine up to the present time.

SYMPTOMATIC THROMBOCYTOPENIC PURPURA

The various causes of secondary or symptomatic thrombocytopenic purpura are listed in the classification given previously. The thrombocytopenia in the peripheral blood in many of these diseases may be associated with an aplasia, with a marked diminution, normal or increased number of bone marrow megakaryocytes.

In *aplastic anemia*, either the primary or secondary type, the hemoglobin, erythrocytes, leukocytes and platelets are usually uniformly reduced in the peripheral blood. There is a relative lymphocytosis and no signs of erythrocyte regeneration. Sternal marrow aspiration will show a hypoplasia of all the bone marrow elements. Secondary aplastic anemia is caused by chemical and physical agents such as x-rays and radio-active substances, or by systemic diseases such as nephritis, metastatic carcinoma, sarcoma, Hodgkin's disease (a rare cause of aplastic anemia) which either destroy or invade and replace (myelophthytic) the normal bone marrow elements. A careful clinical history, physical examination, laboratory data, detailed hematological studies, roentgenograms of the bones, lymph node and bone marrow biopsy many times will suggest the cause of the thrombocytopenic purpura. The same may be said of myelosclerosis.

Pernicious anemia and *chronic hypochromic anemia* may be associated with thrombocytopenia and purpura. The sore tongue, achlorhydria, microcytosis and normoblastic bone marrow, and in pernicious anemia the neurological symptoms, megalocytosis, bilirubinemia, megaloblastic type⁴ of bone marrow and the

rapid response of the anemia and thrombocytopenia to adequate amounts of liver, should make the differential diagnosis simple

Splenomegaly associated with *Banti's syndrome*, *Felty's syndrome*, *thrombophlebitis of portal and splenic vein*, *idiopathic splenomegaly* and *cirrhosis of the liver* with secondary splenomegaly are more often observed with thrombocytopenia than with purpura³⁰ In many of these disorders besides the moderate reduction in the number of platelets, an anemia normocytic or macrocytic in type, leukopenia, neutropenia and a left toxic shift of the granulocytic series are frequent hematologic findings Esophageal varices demonstrated roentgenologically in splenic vein thrombosis, the late stage of Banti's symptom-complex and cirrhosis of the liver, and in Felty's syndrome the chronic deforming arthritis, or intermittently painful joints, cutaneous pigmentation and lymphadenopathy are findings of differential importance in this group of splenomegalic states The bone marrow reveals varying degrees of myeloid, erythroid and megakaryocytic hyperplasia depending upon the stage of the pathologic process Splenectomy is not specific, but with the exception of cirrhosis of the liver the removal of the spleen is followed by a marked clinical and hematological improvement

In *Gaucher's disease* thrombocytopenic purpura has been described a number of times³ The classical findings are splenomegaly, pingueculae, skin pigmentation and the demonstration of the typical Gaucher cells by splenic or sternal puncture

A reduction in the number of blood platelets in association with petechial hemorrhages can occur in *erythroblastosis*, *sickle-cell anemia*, *hemolytic anemia* and *spherocytic jaundice* (congenital and acquired hemolytic icterus) These diseases can be readily differentiated from essential thrombocytopenic purpura by the clinical history, detailed studies of the blood and other appropriate laboratory procedures

In the *acute leukemias* and in the late phase of *chronic leukemia*, thrombocytopenic purpura is a common finding The leukemias can be readily diagnosed by observing in the peripheral blood immature types of leukocytes In doubtful cases with a leukopenia and very few "blast" cells in the peripheral blood, sternal puncture will show a hyperplasia of immature leukocytes, many of which are atypical forms There will be an aplasia of myelopoiesis and megakaryopoiesis

A platelet reduction on the basis of an *allergy* to certain

foods,⁴⁷ orris root, snake venoms, insect bite and pertussis vaccine has been reported. Whether the thrombocytopenia is due to the action of the substance directly on the bone marrow megakaryocytes or caused by a depletion of the circulating platelets is not definitely known. Beneficial results have been reported following the elimination of certain foods, such as wheat, potatoes and milk from the diet of allergic individuals with the symptoms of thrombocytopenic purpura.

Mild or severe purpura and thrombocytopenia may occur during the course of many acute and chronic *infections* (see previous tabulation). Fever, the lack of any evidence of previous hemorrhagic tendencies, blood cultures and blood agglutination tests, blood Wassermann reaction, roentgenological examination of the lungs and throat and sputum examination are a few of the tests that will readily separate the infectious states from essential thrombocytopenic purpura. The bone marrow in practically all of the infections reveals a marked myeloid hyperplasia with a moderate or marked toxic granulopoietic tissue.

Purpura and thrombocytopenia have been repeatedly observed following the administration or contact with a number of *chemicals and drugs* (see tabulation). The granulocytes and erythrocytes may not be affected, although continued action of the chemical on the bone marrow may result in disturbances of granulopoiesis and erythropoiesis with a resulting anemia, leukopenia and thrombocytopenia in the peripheral blood. The *organic arsenicals*⁹ are the best known causes of thrombocytopenic purpura by their toxic effects on the bone marrow megakaryocytes. *Gold salts*, benzol and sedormid¹⁰ may also produce a purpura. I have seen one case of severe, fatal thrombocytopenic purpura following the administration of gold salts for the treatment of arthritis. The bone marrow megakaryocytes showed marked toxic and degenerative changes involving the nucleus and cytoplasm with lack of platelet formation.

Secondary thrombocytopenic purpura following the use of *sulfonamide drugs*¹⁰ has been reported in a number of cases, with death in several of them. The amount of drug necessary to produce purpura is extremely variable. The author observed one case in which a patient was given six tablets of sulfanilamide daily for one week for undulant fever before purpura developed. The bone marrow megakaryocytes were quantita-

tively and qualitatively normal, although the platelet count was less than 50,000. She died of a cerebral hemorrhage.

Thrombocytopenic purpura is rarely caused by *organic hair dyes*² and *leg stocking color preparations*. Sloan⁴⁵ has observed two cases of thrombocytopenic purpura following the use of commercial leg stocking color preparations. In one of these cases studied by me the bone marrow showed a marked diminution in the number of megakaryocytes, while the myeloid and erythroid cells appeared normal.

Congenital thrombocytopenic purpura has been reported in the literature several times. Whitney and Barritt⁵¹ reported its occurrence in two children of the same mother as a result of two consecutive pregnancies.

DIFFERENTIAL DIAGNOSIS

Thrombocytopenic purpura should be distinguished from nonthrombocytopenic purpura, hemophilia, hereditary hemorrhagic thrombasthenia,¹⁷ familial epistaxis,¹⁸ hereditary fibrinogenopenia,³⁴ and hemorrhagic telangiectasia.³⁷

Nonthrombocytopenic purpura occurs in anaphylactoid or allergic conditions, such as *Schonlein-Henoch disease* and *erythema of Osler*, which are characterized by the clinical symptoms of allergy such as erythema, urticaria or effusions of serum into subcutaneous or submucous tissues or viscera. These conditions are mainly the result of increased capillary permeability which allows the passage of plasma and the cellular elements of the blood. There may be a polymorphonuclear leukocytosis and an eosinophilia. The blood platelets, bleeding time, coagulation time and clot retraction are normal. The tourniquet test may be positive or negative. The bone marrow megakaryocytes are not affected.

Many *infections* such as scarlet fever,³³ typhoid fever, subacute bacterial endocarditis, influenza, diphtheria, scarlet fever and septicemias due to various organisms more often produce a purpura without thrombocytopenia. The purpura is either the result of emboli or due to capillary damage produced by toxins.

The nonthrombocytopenic purpura that results from use of *chemicals and drugs* is probably the result of idiosyncrasy. Snake venoms, due to their injury to the endothelial lining of the capillaries, produce multiple hemorrhagic lesions anywhere in the body.

The presence of adequate amounts of ascorbic acid in the body is essential for the proper formation of the "cement substance" between the endothelial cells of the capillary wall. A deficiency of ascorbic acid may result in purpura not associated with a platelet reduction in the peripheral blood.

A miscellaneous group of purpura unassociated with any primary abnormalities of the blood-forming organs include *purpura simplex*, *purpura fulminans*, *purpura senilis* and *purpura cachectica*, *mechanical purpura*, *orthostatic purpura* and *David's disease* which is considered the result of ovarian hormone deficiency.

In *hemophilia* the prothrombin is normal even though the clotting time is prolonged. This is due to the fact that in this disease the platelets are abnormally resistant and therefore yield thromboplastin too slowly to bring about coagulation within the normal time. The clot retraction and blood platelets, as well as the formed elements of the blood, are normal. Anemia, when present, results from excessive bleeding.

*Vitamin K deficiency*⁵ or absence of fibrinogen may cause excessive bleeding with prolongation of both bleeding and coagulation times.

In *hereditary hemorrhagic thrombasthenia*, a type of non-thrombocytopenic hemorrhagic disorder due to defective platelet function, the bleeding time is increased, clot retraction delayed and tourniquet test positive, whereas coagulation time is normal. Purpura is unusual in this disease.

In *familial epistaxis* both the bleeding and coagulation time are normal. Local or generalized abnormalities are not discernible.

In *hereditary hemorrhagic telangiectasia* bleeding may come from telangiectases in any location, although epistaxis is especially common. The anemia results from blood loss and the bleeding time, coagulation time, clot retraction and platelet count are normal.

Polycythemia vera, *erythroleukemia* and *primary thrombocythemia*¹² associated with bleeding tendencies and purpura reveal a normal or more often an increased platelet count, excessive production of erythrocytes, leukocytosis with a normal, leukemic, or leukemoid blood pattern, and a normal bleeding and coagulation time.

Lupus erythematosus disseminatus occasionally is associated

with thrombocytopenic purpura In two cases which I observed the bone marrow showed erythroid, myeloid and megakaryocytic hypoplasia which was reflected in the peripheral blood by anemia, leukopenia and thrombocytopenia

THE TREATMENT OF LEUKEMIA*

HOWARD L. ALT MD†

LEUKEMIA was first described as a clinical entity in 1845. Since that time much knowledge has accumulated concerning the nature of the disease but the cause and a specific treatment remain obscure. Fortunately, leukemia is not a common disease. In Denmark, the yearly total number of deaths is 1 per 50,000 of population. A single physician then would be expected to see few cases during a lifetime of practice.

Leukemia is conveniently classified according to the cells involved, the most common types being myelocytic, lymphocytic and monocytic. It may be further broken down into the acute, subacute and chronic forms. The acute fulminating cases differ sufficiently from the subacute milder cases to warrant this subdivision. The treatment of leukemia is guided almost entirely by whether the disease is acute, subacute or chronic. The cell type is of secondary importance.

A great variety of agents has been used in the treatment of leukemia with varying success in alleviating symptoms and signs. The most important and useful of these are irradiation, arsenic and blood transfusions. To use these agents to the greatest advantage, the individual case must be carefully classified as to the type and the stage of the disease. The management of the patient then continues for the rest of his life. A constant check of the blood picture and the clinical condition is necessary to guide therapy intelligently.

As with other diseases in which a cure has not been established, there is no uniform method of treating leukemia at the present time. Authorities differ greatly in their opinions as to the use of irradiation, arsenic and blood transfusions in various types of cases. The purpose of the present paper is to outline a plan

* From the Department of Medicine, Northwestern University Medical School, and from the Passavant Memorial Hospital, Chicago.

† Assistant Professor of Medicine, Northwestern University Medical School. Attending Physician, Passavant Memorial Hospital.

of treatment of leukemia that has given the author the most satisfactory results over a period of years

In discussing the diagnosis and treatment of leukemia, emphasis will be placed on typical, well defined types of the disease. Actually there are tremendous variations in the symptomatology, course and response to treatment in cases that are classified in the same general group. It is sometimes necessary to follow the course of the disease for some time before the prognosis and the effects of treatment can be determined.

ACUTE LEUKEMIA

Cases are classified as acute leukemia when the onset is rather rapid with high fever and the picture of acute sepsis. There is swelling and inflammation of the gums and the spleen is usually palpable. Adenopathy is common, especially of the cervical group. If the disease is seen very early, there may be little anemia or thrombopenia, but in the course of a few days a progressive decline of the erythrocyte count and platelet count will be noted. As the platelets decrease, there are hemorrhages from the mucous membranes and ecchymoses and petechiae in the skin. The white blood count varies within wide limits, but usually is moderately elevated (25,000 or 50,000 per cu mm). On the blood film, a high percentage of blast cells will be seen. In most cases the cell type can be determined from the more mature leukocytes present, but in some in which most of the cells are in the blast stage the diagnosis of acute leukoblastic or stem cell leukemia must be made. The course may be extremely rapid in these cases. An adult male during a mild respiratory infection had a normal leukocyte and differential count. In a few days he developed the typical picture of acute myelocytic leukemia. The condition grew progressively worse and he expired ten days after the original count was made. Another patient lived only two weeks after the initial symptoms of acute leukemia began. Although the course of the disease is not usually this rapid, it is uncommon for these patients to live more than one to two months.

Treatment has little or no effect on the course of acute leukemia. Irradiation or Fowler's solution are not only of no benefit, but are actually harmful. After such treatment there may be an increase in fever and a more rapid decline in the erythrocyte and platelet count. Blood transfusions cause a transient rise in

the red cell count but the effects are only apparent for a few days. Their use does not warrant the time and expense involved. Any treatment for acute leukemia will only be a gesture for the satisfaction of the patient and his relatives.

SUBACUTE LEUKEMIA

Although acute leukemia, as described above, may merge into the subacute variety, the latter on the whole is much more benign and presents a rather different picture. It occurs in all age groups. The patient with subacute leukemia is frequently ambulatory when first seen for symptoms of weakness, easy fatigue, pallor and afternoon fever of one or two months' duration. A history of spontaneous bruising of the skin is frequently elicited. As often as not, there is no lymphadenopathy and the spleen is not palpable. When present, the enlargement of the lymph glands and/or the spleen is usually slight.

The prominent feature of the blood picture in these cases is the rather marked anemia which may be of the macrocytic type. The erythrocyte counts will be in the range of 1 to 3 million per cu mm. Contrary to the usual conception, leukocytosis is not a constant feature in subacute leukemia. In over half of the cases, the count will be under 10,000 per cu mm and leukopenia is common. A careful differential count practically always reveals a varying percentage of blast cells, which are classified according to the more mature cells present. Complete absence of immature cells in the peripheral blood in subacute leukemia is rare. Lastly, the platelet count is markedly reduced, usually to below 50,000 or 75,000 per cu mm. At times it may be difficult to differentiate subacute leukemia from aplastic anemia. If there is any doubt about the diagnosis, a sternal puncture should be performed. In leukemia the marrow will be found to be hypercellular and contain a high percentage of blast cells. The course and treatment are quite similar whether the disease be of the myelocytic, lymphocytic or the monocytic type.

As the disease progresses there is a continuous fall in the erythrocyte count not unlike that seen in patients with aplastic anemia. The fever increases and there is progressive weakness and loss of weight. Hemorrhagic phenomena secondary to the thrombopenia occur. These patients often have a steady oozing of blood from the gums. Toward the end, patients who have not had a leukocytosis or splenomegaly earlier may have a rapidly

progressive enlargement of the spleen and a sharp increase in the leukocyte count to over a hundred thousand. The average life expectancy in subacute leukemia is four to eight months but since practically all patients receive blood transfusions, the course may be shorter without this treatment.

X-ray therapy has been given a thorough trial in the treatment of subacute leukemia. Almost without exception, there is no benefit or the disease is made worse. The leukocyte count can be reduced with roentgen therapy but there is also a depression of the erythrocyte and platelet counts. One possible beneficial effect of x-ray in subacute leukemia is for the treatment of a local leukemic tumor. An elderly woman with subacute monocytic leukemia had a tumor mass in the nasopharynx which completely obstructed the nasal passages. Local irradiation caused rapid shrinking of the tumor but had no effect on the general disease. Radio-active phosphorus is also without effect in the treatment of subacute leukemia. This might be expected as it is a form of irradiation and does not act very differently from x-rays.

No benefits have been observed from *medicinal therapy* in subacute leukemia. Arsenic in the form of Fowler's solution is contraindicated as it might further inhibit the formation of erythrocytes and thrombocytes. Liver and iron preparations have no effect on the severe anemia. Repeated injections of liver extract might conceivably stimulate myelopoiesis and should therefore not be given to excess, especially in myelocytic leukemia. Vitamins are likewise without effect.

Blood Transfusions

The only treatment that has any real effect on the patient with subacute leukemia is blood transfusion. To be sure, the effect is temporary but any treatment that will improve the patient's feeling of well-being, allow him to be more active, and possibly prolong his life is distinctly worth while. One may wait until the erythrocyte count falls below 2 million per cu mm and the hemoglobin below 6 gm per 100 cc before giving blood. With a count above this level the average patient can be moderately active without symptoms due to anoxemia. Because of the severity of the anemia, it is best to give large transfusions. The donor can spare 100 cc blood per 25 pounds of body weight without the occurrence of untoward symptoms.

The adult patient with leukemia would then receive 600 to 700 cc blood in a single transfusion. Citrated blood has been used in all cases.

Striking effects are noted after a blood transfusion in the early stages of subacute leukemia. The symptoms of fatigue and weakness, which are similar to those seen in toxemia, are markedly improved. If oozing from the gums is present, this is temporarily controlled. A decrease in the size of the spleen was observed in one patient who had slight splenomegaly. The slight to moderate fever is practically always reduced and at times returns to normal for varying periods. Within twelve to twenty-four hours after the transfusion, a considerable reduction in the leukocyte count has been observed and this occurs mostly at the expense of the blast cells. Counts originally of 10,000 to 12,000 per cu mm have decreased to 3000 to 4000 and counts over 20,000 have decreased to less than half the original value. It is unlikely that the above effects are related to the small increase in the erythrocyte count averaging about 500,000 cells per cu mm. It almost seems that there is something in whole blood that temporarily counteracts the leukemic process.

After one to three weeks, depending on the type of the case and the stage of the disease, there is a gradual return of the previous symptoms and signs. In most cases, the erythrocyte count which gradually decreases is used as an index for further transfusions. The patient then leads a "transfusion life" much as does the patient with aplastic anemia. As time goes on, blood transfusions have less and less effect, and are of no value when the patient finally goes into the acute terminal stage.

Occasionally, temporary and partial remissions occur during the course of subacute leukemia. During these times it may be possible to go several months without transfusions. Some of the beneficial effects reported with the use of various agents such as bone marrow or urine extracts may well be related to the simultaneous use of blood transfusions and the occurrence of remissions.

A troublesome feature in leukemic patients who receive multiple transfusions is the occurrence of febrile reactions. No means have been found of preventing such reactions. However, the reactions are seldom hemolytic in nature and the effects seem to be about the same whether reactions occur or not.

The following cases of subacute leukemia illustrate the beneficial effects of blood transfusion

CASE I—A man, aged sixty-two years, was seen in September, 1938, with the complaint of weakness and pallor. The physical examination was essentially negative. The blood picture was as follows: erythrocyte count 1 million per cu mm, platelet count 60,000 per cu mm, leukocyte count 9200, differential—immaturity of the myeloid series. A sternal puncture confirmed the diagnosis of subacute myelocytic leukemia. A series of blood transfusions raised the erythrocyte count to over 3 million per cu mm and he felt practically well. Thereafter because of progressive anemia, he received transfusions of 600 cc blood first at about three-week intervals and later at intervals of ten to fourteen days. He spent several months in Florida during the winter and was able to go away for several weeks the following summer. In October, 1940, over a year later, the spleen became enlarged, the leukocyte count rose rapidly and he died within a few weeks. Over fifty transfusions were given in the course of the illness, during which time he was able to lead a moderately active life.

CASE II—A diagnosis of subacute lymphocytic leukemia was made in a ten-year-old girl in June, 1939. The erythrocyte count was 1.3 million per cu mm, the white blood count was 32,000 with a high percentage of lymphocytes and lymphoblasts, and the platelet count was reduced below 50,000 per cu mm. There was moderate fever and the spleen was palpable. Blood transfusions caused a marked improvement and during the following six months the leukocyte count averaged below 10,000 per cu mm. A gradual increase in symptoms and signs always occurred as the effects of the transfusions wore off. However, the patient remained well enough to attend school the following fall. Symptoms progressed well rapidly in December, 1939, and she died a month later.

Many other cases have shown similar results with blood transfusions.

It is difficult to prove that life is prolonged by repeated transfusions, as no control group is available for comparison. Even though many authors are not enthusiastic about blood transfusions in subacute leukemia, the progressive anemia which is so constant is practically always treated by this means. Without transfusions it is quite possible that death would occur earlier. One can say with certainty that the transfused patient feels

much better and is often able to lead an active life for a fair period of time

Economic difficulties frequently arise when numerous blood transfusions are given. In recent months, it has become common to give *red cell suspensions* from which the plasma has been withdrawn, as a substitute for whole blood in the treatment of anemia. As the expense and trouble involved is much less than with whole blood, it is practical to give large quantities of cells over a short period of time. It is also practical to give the patient red cell suspension transfusions at the office or outpatient department. One patient with a subacute monocytic leukemia has been given several transfusions of red cell suspension of 1000 cc each which is the amount obtained from 2 liters of blood. She felt greatly improved, the anticipated rise in erythrocyte count occurred and there was a reduction in the low grade afternoon fever. It is not yet possible to say whether red cell suspensions will have the same beneficial effects as whole blood in the treatment of subacute leukemia.

Management of the Patient and His Family

There are few patients who try the tact and patience of the physician more than the one with subacute leukemia. It is difficult for the relatives to understand that their loved one, not infrequently a young adult or child who appears in comparatively good health, has not more than six to eight months' life expectancy. The more intelligent and critical relatives will stop at nothing to determine whether someone else has more to offer than their doctor. After exhausting the possibilities in their own community, they often consult specialists and large medical clinics throughout the country. The greatest hope that can be offered is that a cure for the disease might be discovered while the patient's life is being prolonged by blood transfusions.

How much the patient should be told about the nature of his condition depends largely on the individual case. In most instances, it will be better to tell him little. The patient with subacute leukemia should be encouraged to lead as normal a life as possible without producing disagreeable symptoms. It is surprising how much the average patient can do even though he has a rather marked anemia and a moderate fever. The mere fact that he is allowed to lead an active life will give him hope and encouragement for the future.

CHRONIC MYELOCYTIC LEUKEMIA

The clinical picture of chronic myelocytic leukemia is more clearly defined than subacute leukemia and is therefore more familiar to physicians. It is possible that the etiology is different from the acute forms of leukemia. The patient consults the physician because of a feeling of weakness or because of a sense of discomfort in the region of the spleen. Not uncommonly the condition is recognized in the course of a routine leukocyte count. Examination reveals enlargement of the spleen, the size depending on the duration of the disease. The erythrocyte count averages 3 to 4 million per cu mm, the leukocyte count is increased usually to over 100,000 and the platelets are normal or increased in number. The differential count shows a varying percentage of promyelocytes, myelocytes and metamyelocytes.

Roentgen Ray Therapy

Roentgen irradiation has held the most important place in the treatment of chronic myelocytic leukemia since it was used successfully by Senn in 1904. A great number of different techniques have been employed. Earlier it was the custom to give rather large doses of x-rays at frequent intervals. These were given over small areas, the most common sites being the spleen, long bones and chest. Reactions were common and a marked leukopenia sometimes occurred. More recently, smaller doses of x-rays have been favored by most roentgenologists. In 1931, Teschendorf observed good results with the use of *irradiation of the whole body*, so-called "spray" or teleroentgentherapy. Since then, this method has been used by many others and with considerable success. As the leukemic process is widely dispersed in the body, it would seem more logical to treat the patient generally rather than locally. In our clinic, irradiation of the whole body with the exception of the head and genitalia has been used for the treatment of chronic leukemia since 1937. The factors are: voltage 220, milliamperes 20, distance 6 feet, filter 0.5 mm copper plus 1 mm aluminum, time for exposure with equipment used 11 minutes, roentgens 35. The patient is placed across the room from the tube and treatments are given alternately to the front and back of the body. There is rarely any reaction with the dose of 35 roentgens. If a reaction does occur, the dose for subsequent treatments is reduced to 30 roentgens.

A common method of application of x-rays in leukemia is to treat the patient intensively and then to wait for a relapse to occur before giving further treatment. The leukocyte count is usually considered to be less important than other symptoms and signs in determining when treatment is to be reinstituted. This general plan of treatment appears illogical. As the patient with chronic leukemia feels best when the leukocyte count is low and the spleen relatively small, every attempt should be made to maintain this state as continuously as possible. At first the patient is given total body irradiation at weekly intervals until the leukocyte count falls to the range of 10,000 to 15,000 per cu. mm. It should be remembered that the leukocyte count continues to decrease for a week or longer after each irradiation. Following treatment there will be a marked improvement in strength, the spleen decreases in size until it may be no longer palpable, and the erythrocyte count increases by 500,000 to 1 million cells per cu. mm. In this state, the patient may feel perfectly well and should be encouraged to live a normal existence. Subsequently a leukocyte count is made every two to 4 weeks and the size of the spleen recorded in fingerbreadths below the costal margin. As the leukocytes increase to over 15,000 or 20,000 per cu. mm and a slight increase in the size of the spleen occurs, another treatment is given. The intervals between x-ray treatments depends largely on the individual case. Some patients can be maintained in a fair state of remission with treatments every two to three months, whereas others require them more often. This so-called continuous treatment of leukemia was advocated by Murphy in 1940.

Radio-active Phosphorus

A new method of irradiation which has been in use for three years and shows great promise is radio-active phosphorus. Its advantage over x-rays is that it can be given orally, there are no reactions, it is specifically absorbed by the leukemic cells and it has a continuous action for over fourteen days. Lawrence and his co-workers have observed prolonged remissions in chronic leukemia with the repeated administration of radio-active phosphorus. Unfortunately, this substance is not available for general use at the present time. It would seem that the continuous treatment with total irradiation described above is an approach to the principle of treatment with radio-active phosphorus.

Arsenic Therapy

An adjunct to irradiation in the treatment of chronic myelocytic leukemia is solution of potassium arsenite (Fowler's solution) After being almost forgotten for many years, Forkner and Scott revived interest in arsenic in 1931 They demonstrated an effect similar to that of irradiation in patients with chronic myelocytic leukemia. The disadvantages of Fowler's solution are the frequent occurrence of toxic symptoms, such as weakness, anorexia, nausea and vomiting, diarrhea and herpes zoster and the fact that a relapse may occur even while treatment is continued It has been found that significant toxic symptoms can be largely avoided if Fowler's solution is given in smaller doses and over a shorter period of time than recommended by Forkner and Scott. The method has been to give 3 minims three times daily the first day and to increase the dose one minim each day up to 10 or 12 minims three times daily At the first indication of toxicity, the drug is omitted for one day and then resumed at a dose one minim less than that which caused the reaction This dose is continued through a period of twenty-one days from the time the arsenic was first given This amount of treatment will usually cause an appreciable drop in the leukocyte count and a decrease in the size of spleen, the maximum effect occurring about seven to ten days after treatment, is stopped In order to avoid any cumulative effects, a rest period of six weeks is allowed before another course of the drug is given

Arsenic and Roentgen Therapy Alternately

To maintain a continuous remission, it has been found very satisfactory to alternate arsenic therapy with roentgen therapy Fowler's solution is given for a period of three weeks as outlined above If in the six weeks following, the leukocyte count rises above 15,000 per cu mm., one or more total irradiation treatments are given Thus the patient remains in remission and avoids the expense and trouble of taking as many x-ray treatments as otherwise would be required One patient with chronic myelocytic leukemia received alternating arsenic and x-ray therapy over a period of five years He worked the entire time and for the most part enjoyed excellent health His disease was always easier to control during the summer months at which time he worked outside in the sun During these times it was

often unnecessary to give roentgen therapy between the courses of Fowler's solution. The beneficial effect of sunlight was also noted by Poole and his associates in 1938.

Terminal Stage, Duration of Life

In all patients with chronic myelocytic leukemia there comes a time when x-ray and arsenic treatment is no longer effective and may even be harmful. The turning point may become apparent within the course of a few weeks and is characterized by weakness, fever, a decline in the erythrocytes and platelets, and an increasing number of myeloblasts in the blood film. After these signs appear, the life expectancy is not more than a few months at most. This terminal stage of the disease should not be confused with the acute picture that is sometimes seen in the chronic stage, as illustrated in the following case.

CASE III—A male, aged twenty-two years, was seen who had had symptoms of leukemia for over a year but had never received Roentgen therapy. He was emaciated and had a high fever. His spleen filled the entire left half of the abdomen. The erythrocyte count was 2 million per cu mm and the leukocyte count 2.5 million per cu mm. The blood film showed a great preponderance of promyelocytes but relatively few myeloblasts. The platelets appeared normal in number. His physician and roentgenologist felt that x-ray therapy was contraindicated because of the acuteness of the condition. As the blood picture was compatible with the chronic stage of myelocytic leukemia, however, a series of x-ray treatments were given. The leukocyte count returned to normal, the spleen decreased greatly in size and he was able to be ambulatory in a few weeks. Death occurred one year later.

The average duration of life in chronic myelocytic leukemia is said to be about three to four years but many patients live much longer. It is the consensus that life is not significantly prolonged by the use of roentgen or arsenic therapy. One wonders how accurate are these statistics. In a small series of patients who were given "continuous" total irradiation therapy, Murphy felt that life was prolonged greater than in another series treated by the interval massive dose technic. Regardless of whether life is or is not prolonged, the maintenance of these patients in a state of relatively good health and economic efficiency justifies the treatment given.

CHRONIC LYMPHOCYTIC LEUKEMIA

The clinical picture and course of chronic lymphocytic leukemia resemble the myelocytic type. The disease occurs preponderantly in individuals over forty-five years of age. Although the life expectancy is said to be about three and one-half years, the cases on the whole have run a more benign course in the lymphocytic group. The diagnosis of chronic lymphocytic leukemia is not infrequently made during a routine examination. In the earlier stages, there is slight to moderate enlargement of the lymph glands, spleen and liver. The leukocyte count is usually over 100,000 and about 90 per cent of the cells are mature lymphocytes. Slight reduction of the erythrocyte and platelet counts is common.

In the last few years, several cases have been recognized at a very early stage. The only positive findings were leukocyte counts between 25,000 and 35,000 per cu mm and a high percentage of lymphocytes in the blood film. No treatment is indicated in this phase of the disease, which may continue for some time.

In the more advanced cases, with lymphadenopathy, splenomegaly and leukocyte counts over 100,000 per cu mm, *total body irradiation* is given according to the method described for chronic myelocytic leukemia. After remission is established, the blood picture is studied at intervals of one to two months and an x-ray treatment is given whenever the leukocyte count goes over 20,000 or 25,000 per cu mm. Our patients with lymphocytic leukemia have for the most part required less treatment to remain in remission than have the myelocytic group.

CASE IV—A woman, aged sixty-two years, was seen three and one-half years ago with a markedly enlarged spleen, a slight generalized adenopathy and a leukocyte count of 350,000, with 95 per cent mature lymphocytes. Following the initial treatments, she has received total irradiation on the average of every two to four months. The leukocyte count has varied from 15,000 to 35,000 and the spleen has remained palpable from 2 to 3 fingerbreadths below the costal margin. There is only slight adenopathy. The leukocyte count decreases after each x-ray treatment and then gradually rises before the next treatment is given. From the time that the disease was brought under control, she has remained entirely free of any symptoms. She has suffered no reactions from the x-ray therapy.

As with myelocytic leukemia, the lymphocytic type also reaches a stage when irradiation is no longer effective. At this stage there is fever, a progressive anemia and a fall in the platelets, usually to below 50,000 per cu mm. In the cases that have been seen in an advanced stage of chronic lymphocytic leukemia, lymphoblasts were not present in the peripheral blood.

One cannot always be certain that the patient has passed the stage when x-ray treatment will be effective, as evidenced by the following history:

CASE V—Recently, a male, aged sixty-six years, entered the hospital with a history of chronic lymphocytic leukemia of seven years' duration. He was thin and dyspneic. There was marked lymphadenopathy, the spleen extended to the pelvis, the liver was enlarged, and there was extensive edema of both legs. The blood picture was as follows: erythrocytes 1.4 million per cu mm., leukocytes 750,000 per cu mm., differential count 98 per cent mature lymphocytes and the platelets 48,000 per cu mm. After two red cell transfusions, a series of total body irradiation treatments was given. When next seen two months later the patient felt markedly improved and was able to work every day. The erythrocyte count was then 3.2 million per cu mm. and the leukocytes 20,000 per cu mm. The spleen and lymph glands had decreased in size and the edema had disappeared. When this patient was first seen, his chance of being benefited by x-ray treatment seemed remote.

Solution of potassium arsenite is relatively ineffective in the treatment of chronic lymphocytic leukemia.

In conclusion, it is apparent that much can be done to make the patient with leukemia feel better and to give him months or years of active living. Until a specific cure for leukemia is discovered, it is the physician's responsibility to use the available methods of treatment to the greatest advantage.

SUMMARY

For the purpose of treatment, leukemia is classified into the acute, subacute and chronic types. In acute fulminating leukemia, no treatment is of any avail. Blood transfusions cause considerable temporary benefit in the subacute types of leukemia. For the treatment of chronic leukemia, total body irradiation given at intervals to maintain continuous remission is

avored X-ray therapy* used alternately with short courses of Fowler's solution (solution of potassium arsenite) also gives satisfactory results. With the proper use of irradiation, arsenic and blood transfusions the patient's general health and economic efficiency can be maintained for long periods.

* The x-ray therapy in these patients was conducted by Dr. Earl E. Barth.

HODGKIN'S DISEASE

RAPHAEL ISAACS M.A. M.D., F.A.C.P

HODGKIN's disease presents many problems both in diagnosis and treatment. With the cause unknown, many types of clinical manifestations and a difficult differential diagnosis, the condition warrants careful study. In the absence of a specific treatment, emphasis must be placed on what not to do.

PRESENTATION OF CASES

The two cases presented here illustrate a benign and a malignant type, and emphasize certain features in diagnosis and treatment.

Case 1 Benign Type

History—The first patient, a young woman of twenty-six years, had considered herself well until about three years ago. At that time she noticed a "swelling" in the left pectoral region. The doctor watched it during the course of two months and as it did not respond to simple medication, it was removed. The mass proved to be an enlarged lymph node, and study of it led to a diagnosis of Hodgkin's disease. As frequently happens, as soon as the word "Hodgkin's" was mentioned the patient was rushed to a roentgen ray machine. Six treatments were given over the mediastinum, supraclavicular regions and left axilla.

One wonders why roentgen ray treatments were given. There is a mistaken impression that roentgen therapy is prophylactic, and that it will prevent growth of glands. In reality, in Hodgkin's disease, it reduces the number of lymphocytes, a process that is taking place as a part of the morbid condition.

At that time the blood was reported as "normal." In the early stages, when one lymph node is involved, there may be no gross change in the blood, quantitatively or qualitatively. Occasionally there is an increase in the number and percentage of lymphocytes, and plasma cells may be present in the blood stream. There is no basophilia of the granules of the neutrophils, as one would expect

in a pyogenic infection. As the disease progresses, other changes take place, and these will be discussed later.

Subjective symptoms developed slowly in this patient. She did not feel sick, but she tired easily. This is a common symptom, often one of the earliest in this disease as in many others. The exact mechanism of this symptom is not clear. It is not necessarily anemia, since it appears when the blood count is within normal limits. It appears when the urine is acid or alkaline, and is not correlated with any of the common blood chemical constituent variations. Occasionally there are symptoms of myocardial weakness, manifesting itself in shortness of breath on exertion. This however may be an evidence of generalized muscular weakness—an effect rather than a cause. There is a “sinking” feeling in the legs, amounting to actual pain at times.

This patient lost her appetite, ate less, and her weight decreased from 118 pounds to 105 pounds during the course of the first year. Her doctor prescribed “vitamins,” an arsenic preparation, and calcium salts. In spite of large quantities of mixtures of the various vitamin B components, as well as vitamins A and C, there was no therapeutic response. The arsenic was given because arsenic is given in Hodgkin’s disease. The calcium was for bleeding of the nose, a disability which she had noted since the age of fourteen or fifteen years. She noted but few of the common early symptoms of Hodgkin’s disease, such as pruritus, cough, fever, or pain.

A year after the appearance of the first symptom, enlarged lymph nodes developed on the left side of her neck and the left axilla. These receded after a second series of roentgen ray treatments. The unilateral appearance of enlarged lymph nodes, later bilateral, is characteristic of Hodgkin’s disease.

Physical Examination—The patient was first seen by us about four months after this episode. She was a slender, fairly well developed individual who tired easily. The cervical glands were not enlarged, but there were two small nodes palpable in the left anterior triangle and one in the left axilla. They were discrete, hard, not tender and not adherent to the skin. The spleen was enlarged to 15 cm on the left, and the liver to 16 cm in the right mid-clavicular line. There was no gross abnormality of the heart, lungs, gastro-intestinal tract, or genito-urinary system.

Blood Picture—The blood at this time showed erythrocytes, 3,740,000 per cubic millimeter, leukocytes, 7300, hemoglobin, 10.4 gm per 100 cc, polymorphonuclear neutrophils, 80 per cent, lymphocytes, 5 per cent, monocytes, 5 per cent, eosinophils, 4 per cent, basophils, 1 per cent, cells noted in infectious mononucleosis, 2 per cent, endothelial cells, noted in conditions in which the liver is enlarged, 2 per cent, plasma cells, 1 per cent. The platelets were

increased in number Basophilia of the granules of the neutrophils was positive.

There was a moderate anemia, with "iron-deficiency" The polymorphonuclear neutrophils were increased in number and the lymphocytes definitely decreased This was about four months after the roentgen ray therapy, making it unlikely that the lymphopenia was one of the sequelae of this irradiation The presence of plasma cells indicated that pathological activity was going on in lymph nodes The infectious mononucleosis cells suggested possibilities for speculation Was the original disease an attack of infectious mononucleosis and were the subsequent developments pathological processes stirred up by the roentgen ray therapy? Against this was the pathologist's word that the gland removed was "Hodgkin's disease" Certainly the tissue showed the large Greenfield-Sternberg-Reed cells She may have had an attack of infectious mononucleosis at some time in her life, with the production of some of the abnormal cells for long periods thereafter (infectious mononucleosis cells have been recognized in a patient's blood seven years after an attack of the disease) Cells of this type were noted in this patient's blood during the next two months after which they were only rarely found

Treatment and Course—For treatment, several factors had to be considered There was the general nutrition, which was below par, there was a mild iron deficiency anemia, and the number of lymphocytes was low

For the improvement of the general nutrition an adequate diet was prescribed However financial considerations, rationing, as well as difficulty in preparing food in the room where the patient lived, made gain in weight a difficult problem Large quantities of "vitamins" of all kinds failed to influence either the appetite or weight

To improve the hemoglobin picture, we prescribed ferrous sulfate, 4 grains, three times a day There was no improvement during the course of three weeks A preparation of ferrous sulfate (10 grains per day) which contained some liver and "vitamins" was then substituted The hemoglobin increased from 10.4 gm per 100 cc to 12.6 gm in two weeks Thereafter the hemoglobin fluctuated from a low of 10.2 gm to 13.6 gm, depending on the profuseness of her menstruation

The erythrocyte count fluctuated from a low of 3,670,000 per cubic millimeter to 5,000,000

During the course of seventeen months the total leukocyte

count rose gradually from the lowest point of 6300 per cubic millimeter to 15,000

As Hodgkin's disease is "lymphotoxic," with a decrease in the number of lymphocytes in the blood stream as the disease progresses, an effort was made to increase the number of lymphocytes. Exposure to sunlight was always followed by the development of a rash, and had to be limited. The patient was then given an experimental extract of lymph glands, 1 gm daily. During the course of the seventeen months of observation, the number of lymphocytes increased from 584 per cubic millimeter to 1666 per cubic millimeter.

After seventeen months there are no changes in the two palpable lymph nodes, about 2 cm in diameter, in the anterior cervical triangle on the left side, and a similar node is palpable in the left axilla. The patient works regularly, and for all practical purposes appears in fairly good health. The progressive leukocytosis and the persistence of the palpable glands show that the underlying disease is still present. The peculiar papular rash developing on the extremities after exposure to sunlight has been diagnosed as "sun allergy." It must be remembered that skin lesions of many kinds appear during the course of Hodgkin's disease.

Case II Malignant Type

Other features of Hodgkin's disease (rapid course, effect of too much roentgen ray therapy, and the development of features of a malignant neoplasm) are illustrated by the following case.

History—The patient is a man of forty-nine years, who considered himself in good health until about three months ago. He then noticed weakness, fever and developed pallor. The onset was rather rapid although the development of the symptoms covered three or four weeks. He went to a hospital where it was noted there was generalized enlargement of the lymph glands. One was removed, and the puzzled pathologist considered that it was a malignant tumor of some kind, possibly reticulum cell sarcoma or metastatic carcinoma. Roentgen ray therapy was started at once, with exposures over the anterior and posterior aspects of the mediastinum, the supraclavicular spaces, the inguinal regions, and both axillae. A total of 1850 roentgen units of irradiation was given in eleven days.

Physical Examination—The patient was first seen by us after the last treatment. He appeared pale and sick. He had a paroxysmal nonproductive cough. The peripheral lymph glands, including the epitrochlears, were enlarged. The tonsillar areas were depressed and the anterior pillars congested. There was an abnormal widening of the mediastinal dulness. In the first to the fourth interspaces, with the patient lying down, the dulness extended 5, 6.5, 6.5 and 5.5 cm. to the right of the midline, and 7, 11, 12, 13 and 11 cm. to the left. The pulse rate was 84 and blood pressure 100 systolic and 70 diastolic. The liver was enlarged to 16 cm. in the right mid-

Fig. 35—Enlarged hilar lymph glands (Case II)

clavicular line. The spleen measured 17 cm., but was not palpable. The dulness in the right hilar region posteriorly was enlarged to 16 by 8 cm. and on the left 16 by 10 cm. The enlarged hilar and mediastinal dulness indicated enlarged glandular masses, confirmed by roentgenographic examination (Fig. 35).

Blood Picture—The blood showed 4,000,000 erythrocytes per cubic millimeter, leukocytes, 11,000 per cubic millimeter, hemoglobin, 14 gm. per 100 cc. polymorphonuclear neutrophils, 74 per cent, lymphocytes, 4 per cent, monocytes, 22 per cent. Platelets were increased in number and vacuolated monocytes were present. The urine was not abnormal.

Treatment and Course—Although it had been the intention of the original operator to give more roentgen ray therapy, the patient was advised to discontinue it, as the lymphocytes numbered only 440 per cubic millimeter. It was felt that the findings on physical examination, as well as the blood picture (polymorphonuclear neutrophil leukocytosis, monocytosis, increased number of blood platelets, lymphopenia, increased by roentgen ray therapy) were compatible with the diagnosis of Hodgkin's disease.

During the next four weeks the leukocyte count decreased to 2000 per cubic millimeter and the number of lymphocytes fell to 240 per cubic millimeter. The erythrocyte count fell rapidly to 1,600,000 per cubic millimeter. A sternal puncture at this time showed practically complete aplasia of the erythrocyte-forming tissue and moderate hypoplasia of the leukocyte tissue. It was necessary to give ten blood transfusions in order to keep the erythrocyte count just over three million per cubic millimeter. On four consecutive days, 500 cc. of packed red blood corpuscles were given. This was equivalent to 4000 cc of whole blood. It caused an increase in the erythrocyte count from 2,000,000 to 3,470,000 per cubic millimeter.

A punctate rash appeared over the whole body, with edema of the face and legs. It was felt, at first, that this was a manifestation of Hodgkin's disease, but it was found that a previous doctor had prescribed phenobarbital, and that the patient had been taking this regularly for some weeks. The rash gradually faded and disappeared when the medicine was discontinued, and desquamation followed. The temperature ranged from 99.2 to 101°F, usually higher in the afternoon, but following no set pattern.

A lymph gland was removed and showed total loss of the normal architecture, with replacement by lymphoid cells, which invaded the capsule and surrounding tissues. There were many Greenfield-Sternberg-Reed multinucleated giant cells, with overlapping nuclei, and increased formation of connective tissue. This tissue had the characteristics of Hodgkin's sarcoma or reticulum cell sarcoma.

Prognosis—This type of Hodgkin's disease differs from that in the first case in that a lymphoid type of cell becomes "neoplastic," grows rapidly, and invades the surrounding tissues. There is generalized involvement of all the lymph tissue in the

body, including the mediastinal and abdominal glands. The vacuolated monocytes indicate that the gallbladder-bile duct apparatus is interfered with, and the enlarged regional nodes are causing obstructive pressure. Aplasia of the marrow has been caused by excessive roentgen irradiation. The prognosis now is extremely poor.

DISCUSSION

Terminology

Hodgkin's disease is known by many names in the literature: lymphogranuloma, pseudoleukemia, malignant granuloma, Sternberg's disease, Hodgkin's granuloma, Hodgkin's sarcoma, sarcomatous Hodgkin's disease. While many object to the use of an individual's name in designating a disease, everyone knows what is meant by Hodgkin's disease, whereas some of the other terms, having been used for other conditions, are confusing. Dorothy Reed¹ postulated: "We should limit the term Hodgkin's disease to designating a clinical and pathological entity, the main features of which are painless progressive glandular enlargement, usually starting in the cervical regions, without blood changes of leukemia. The growth presents a specific histological picture, not a simple hyperplasia, but changes suggesting a chronic inflammatory process. Eosinophiles are usually present in great numbers in such growths, but not invariably."

Incidence

The disease involves individuals at all ages, but is two to three times more frequent in males than in females. There are less than 2000 deaths (average for the years 1934-1936 was 1614) per year known to have occurred from this disease in the United States. The rate is increasing slowly, being 0.6 per 100,000 for white men and 0.3 for white women in 1921 and 1.5 for white men and 1 for white women in 1937 in the standardized statistics of the Metropolitan Life Insurance Company. The percentage distribution of deaths for an average year (1936) was: Under fifteen years, 7.34 per cent; fifteen to forty-four years, 40.52 per cent; forty-five to sixty-four years, 34.87 per cent; sixty-five and over, 17.27 per cent.

At present, little can be said of the *etiology* of the disease. The problem is reviewed by Krumbhaar.²

Diagnosis

Diagnosis is based on the clinical symptoms and course, on the blood changes, and on the study of sections of lymph glands

Clinical Symptoms—Symptomatology is the result of enlargement of the glands (pressure, pain, obstruction, dysphagia, engorged veins, pleural effusion, ascites, cough, diarrhea, constipation, jaundice, dyspnea, pulmonary symptoms, albuminuria, or edema), from associated toxemia (cachexia, loss of weight, fever, lesions of the skin, pruritus, headache, nausea, vomiting, weakness, mental depression, lymphopenia, chills, insomnia, anemia, leukocytosis, or elevated basal metabolic rate), or from metastatic growths or infiltrations (skin lesions, bone marrow invasion, bone lesions and neurological symptoms)

SYMPTOMATOLOGY FROM ENLARGED LYMPH GLANDS IN HODGKIN'S DISEASE

Cervical, Submaxillary, Sublingual and Parotid Regions

Pain in head and neck
Difficulty in moving neck
Dysphagia
Pain in shoulders
Dry mouth
Pain in ear
Pupillary changes
Tachycardia
"Bad taste in mouth"
Headache

Axillary Glands

Pain in shoulder and arm
Edema of hand or arm
Difficulty in moving arm
Weakness of arm

Mediastinal and Hilar Glands

Cough
Dyspnea
Dysphagia
Tachycardia
Nausea
Pleural effusion

Inguinal Glands (Superficial and Deep)

Pain in leg
Edema of foot or leg
Difficulty in walking
Pain and edema of scrotum
Weakness of legs

Lumbar and Abdominal Glands

Diarrhea
 Constipation
 Abdominal pain
 Pruritus
 Pain in back
 Jaundice
 Fever
 Nausea
 Anorexia
 Ascites

Spleen

General weakness
 Giddiness and dizziness
 Headache
 Constipation or diarrhea
 Pain in left upper quadrant of the abdomen
 Vomiting
 Nausea
 Cough
 Palpitation
 Feeling of fullness or dragging in left upper quadrant of the abdomen
 Abdominal discomfort
 Midpigastrie pain
 Anorexia
 Fever
 Jaundice
 Pain on deep inspiration
 Pain in left side of chest
 Pain in left shoulder
 Tenderness over the spleen region
 Pain in the "back"
 Pain in the left leg
 Discomfort in certain positions
 Night sweats
 Hemorrhoids
 "Buzzing" in the ears
 Gastro-intestinal upsets
 Difficulty in bending
 Tenderness of trapezius or left deltoid muscles
 Dysphagia
 Soreness of the inner surface of the left thigh
 "Tightness" of the left knee
 Swollen left testicle
 Friction rub in left axilla
 Pain in left arm
 Visual disturbances
 Left pupil smaller than the right
 Elevation of cardiac apex (pseudo left axis deviation in electrocardiogram)
 Congestion of abdominal blood vessels
 "Heartburn"

A characteristic type of fever (Murchison, Pel-Ebstein) has been described. This is marked by a gradually increasing fever which reaches a maximum and then declines to a normal level. The febrile period and nonfebrile periods may last from two weeks to months. However, in actual practice, perfect examples of this type of fever are seldom seen. No doubt the use of aspirin, roentgen ray therapy and antifebrile measures disturb the picture. Great debility and enervating perspiration may accompany these periods.

In many individuals symptoms of an elevated basal metabolic rate may appear, with perspiration, rapid pulse rate, tremors, loss of weight, irritability and nervousness.

Blood Changes—The blood changes in Hodgkin's disease vary with the type and the stage of the disease. In the advanced stages there is a progressive anemia, either from hypoplasia of the marrow or from development of the Hodgkin's growth in the marrow cavity. The anemia is usually of the hypochromic type, with some cases showing considerable variation in the size and shape of the erythrocytes, occasionally stippled cells, rarely normoblasts. In the type with the aplastic bone marrow, the erythrocytes may be uniformly round and show but little variation in size. The erythrocyte count may, however, remain within normal limits for years. As the disease progresses, the erythrocytes, in films, may show marked rouleau formation and autoagglutination, reflected in a rapid sedimentation rate.

The platelets are usually increased in number, and the bone marrow shows an increase in the number of megakaryocytes.

There are two types of the disease as evidenced from the leukocyte count. In one type, the "uncomplicated" Hodgkin's disease, there is a tendency for the leukocyte count to increase, commonly to 15,000 to 18,000, occasionally to 50,000 or over 100,000 per cubic millimeter. As a rule the leukocytosis is neutrophilic in type, occasionally eosinophilic. The eosinophils, commonly increased in number in the lymph glands and tissues, may or may not be increased in number in the blood. The Gordon test runs parallel to the number of eosinophils, and is not a specific test for Hodgkin's disease. With the progress of the disease the lymphocytes decrease in number to extremely low levels. The monocytes may be more numerous than normal. The first case described here illustrates this type.

In the second type, corresponding to the sarcomatous Hodg-

kin's group, including the variety called Hodgkin's sarcoma, the leukocyte number is not increased, or is quite low. The number may be from 1000 or 2000 to 6000 per cubic millimeter when the disease begins to become well developed. In this type the absolute lymphocyte number may be decreased, although relatively the percentage may not be as low as in the other type of Hodgkin's disease. The second case described here is of this type.

Occasionally small forms of the Greenfield-Sternberg-Reed cells are found in the blood film. They may be mistaken for atypical monocytes. Plasma cells are noted frequently. Bone marrow puncture is helpful in ruling out other lesions, although rarely the needle may enter a region of Hodgkin's tissue, and is then of direct diagnostic value.

The two types of blood picture, as well as the secondary changes which follow roentgen ray therapy, have led to the general statement that there is no characteristic blood picture in Hodgkin's disease.

Prognosis

The prognosis varies with the rapidity of the disease process and the caution used in treatment. There are rapidly growing and slowly growing forms of the disease, and a rare acute form is encountered. Some patients survive twenty-six years or more, whereas others live but a few months. The variations are so great that the term "average duration" has but little significance at present. Certain features suggest a bad prognosis: high or progressive fever, short duration of remissions after roentgen therapy, progressive and marked anemia, gross involvement of the abdominal lymph glands, generalized involvement of all the glandular areas, coincident disease of other types, as tuberculosis, progressive cachexia, excessive and unwise roentgen therapy.

Treatment

For treatment, the use of roentgen rays, radium or radioactive substances appears to be most effective in relieving symptoms. Irradiation is not prophylactic or curative. It is wise to limit the treatment to the lowest possible exposure and to avoid it when the lymphocyte count is low. The virtual wiping out of the lymphocytes in the second patient described here, and the production of erythrocyte aplasia of the marrow are examples

of treating the lymphoid tumors and forgetting the patient. Much improvement may follow proper roentgen ray treatment of the bone lesions which may be present in the disease.

Long remissions have followed removal of isolated, diseased nodes. We have seen a flare-up of the disease in cases of removal of part of the nodes, with others remaining in the region. The biopsy wound, however, is not involved in the process, as may follow in tuberculosis or lymphosarcoma. Blood transfusion, when needed, is a valuable temporary measure. Arsenic in the form of Fowler's solution appears to have a beneficial effect on the disease as a whole in a few patients, but does not help others. It may accentuate the normal tendency to pigmentation in this disease.

Any therapy which would tend to increase the number of lymphocytes would be of value. Sunlight and ultraviolet irradiation appear to have some value, although it is limited. Certain experimental extracts of lymph glands appear to have value in cases which have not advanced too far. For the fever, aspirin and tepid sponges give subjective relief.

Cough may be a severe and difficult symptom. Frequently it is the result of enlarged mediastinal or hilar lymph nodes (Fig 35). Codeine and the commonly employed cough medicines are usually ineffective. Some relief may follow roentgen ray therapy over the mediastinum or the hilar nodes. When the nodes become sclerotic, little help can be expected from roentgen ray therapy.

Herpes is a troublesome complication. Locally "carbulated vaseline" or similar preparations may give temporary relief from pain. Roentgen ray therapy over the vertebral region may be tried. Some patients are helped by the intravenous administration of sodium iodide, 15 grains in 10 or 20 cc of water on two or three consecutive days.

Pruritus may respond to roentgen ray therapy over the vertebral region, especially in the lumbar part. Local and internal medication is seldom helpful. The usual antipruritic substances, especially phenol, may give temporary relief. Tincture of belladonna, 10 minims, three times a day before meals may be tried. Among the supportive measures advocated are the administration of iron, viosterol, vitamins and iodides. The results vary considerably from patient to patient.

The prognosis in Hodgkin's disease is not necessarily as

gloomy as the earlier accounts indicated Treatment must be given extremely carefully, as more damage may be done by over-treatment or unwise treatment than would be done if no treatment at all had been given Much good may be accomplished by proper therapy

PERNICIOUS ANEMIA*

STEVEN O. SCHWARTZ, M.D.

DEFINITION

PERNICIOUS anemia is a disease usually insidious in onset and protracted in course, manifesting itself as an involvement of the hemopoietic, gastro-intestinal and nervous systems with differing degrees of intensity. Involvement of the hemopoietic system results in a megaloblastic bone marrow and varying degrees of anemia, leukopenia, granulopenia and thrombocytopenia. Prime manifestation of gastro-intestinal involvement is the atrophy of the gastric mucosa with an accompanying achlorhydria and achylia, while degenerative changes of the posterior and lateral columns of the spinal cord characterize the nervous system changes. The administration of liver induces a remission in the manifestations of the disease.

HISTORY

Thomas Addison is credited with the original description of pernicious anemia, though his concept of the interrelationship with suprarenal gland disease was incorrect, and several writers recorded the disease before him. His masterly description published in 1855¹ has well earned him the eponym, albeit in strict justice credit for priority should go elsewhere. Combe¹⁶ in 1822 is said to have been the first to report an authentic case, while others were published by Andral (1823), Hall (1837), Piory (1841), Pearce (1845),³¹ Elliotson (1846),¹⁹ and Barclay (1851).⁶ Channing as early as 1842,¹³ recognized a severe pernicious anemia-like picture in the puerperium and discussed the use of blood transfusions in its treatment. Biermer,⁸ unaware of Addison's work, reported fifteen cases in 1871 and is often credited by German writers with priority, even though another German, Lebert, had published two cases previously.

* From the Hematological Laboratory, Cook County Hospital. Aided by a grant from the Wilson Laboratories.

By 1860 when Wilks pointed out the absence of an increase in the white blood cells, much interest was manifested in both the clinical and pathological aspects of the disease. Greatest progress, in retrospect, was made between 1874 and 1888. In 1874 Immerman called attention to the fever which accompanied the disease (an association also noted by Biermer) and attributed it to the anemia. In 1875 Pepper and a year later Cohnheim¹⁵ described accurately for the first time the changes in the marrow and suggested that these were responsible for the anemia. During the same year Quinke¹⁵ depicted the rich iron deposits in the liver, pancreas, kidneys and other organs and pointed out the difference in the size of the red blood cells, calling attention to their variations in shape, which he named poikilocytosis. The next year Bromwell was reporting favorable results in some cases following the administration of arsenic, and three years later Fenwick²¹ not only recorded that the gastric mucosa was atrophic but clairvoyantly expressed the view that the symptoms of the disease were the results of this rather than the secondary deficiency of the blood. Between 1880 and 1883 came Ehrlich's discovery of nucleated red cells in the circulating blood, Eichhorst's finding of the microcytes, and Laache's observation on the disproportionately high hemoglobin-red cell ratio and emphasis of the large, deeply colored red cell which he thought characteristic. Soon afterwards Lichtheim (1887) recognized the pathological, and resultant clinical, nervous system changes.

Momentum was given the theory of parasitic etiology by the findings of *Ankylostoma duodenale* by Baumler (1881) and Sahl (1883) and *Dibothriocephalus latus* by Rehber (1884) and Runberg (1888) in cases of apparent pernicious anemia. But Hunter, basing his thesis on the increased stores of iron, the hyperplasia of the bone marrow, and evidences of blood destruction, postulated a toxic, hemolytic causation.

There is little of significance, excepting the increasingly widespread use of blood transfusions and the brief era of splenectomy, separating these early years from the "modern" era. Basing his observations on the efficacy of liver in relieving dogs made anemic by bleeding, Whipple⁶⁰ suggested that there might be a scarcity of red cell stroma building material in pernicious anemia. Minot, prompted by this work and the knowledge that liver was of benefit in sprue, together with Murphy⁴² began

feeding large amounts of liver to patients and by 1926 had become satisfied with both the objective and subjective response to this therapy. Soon Cohn and Minot¹⁴ were able to show that oral extracts of liver were as efficacious as the whole organ, and not long afterwards Ganssle prepared the first practical parenteral extract.

The next milestone is represented by Castle's experiments^{11, 12} showing that pernicious anemia is the result of a lack of the so-called "intrinsic factor," which is normally produced by the stomach and interacts with certain foods containing the "extrinsic factor" to produce the "anti-pernicious anemia principle." Sturgis and Isaacs⁶¹ (1929) showed that stomach tissue had properties similar to liver, and since then these properties have been demonstrated in kidney, brain, placenta and other organs. Much has been written and many of the finer clinical and hematological details clarified in the intervening years, but with the exception of the concentration of the liver extract and attempts at the establishment of its chemical identity, with the view of synthesis, no further progress has been made.

ETIOLOGY

Pernicious anemia results from the failure of the gastric mucosa to elaborate the "intrinsic factor" of Castle, which is normally produced in the pyloric portion of the stomach in man.³⁰ When the "intrinsic factor" is absent or markedly diminished,^{26, 29} no "anti-pernicious anemia principle" is formed by interaction with the "extrinsic factor."⁵⁹

The "anti-pernicious anemia principle" is stored in the liver⁵¹ and thence supplies the functional needs of the bone marrow, the integument and its appendages, and the central nervous system. Occasionally destruction of the "intrinsic factor" producing portion of the stomach by disease,²⁵ chemicals,² or surgery⁴⁰ will give rise to pernicious anemia. Infrequently, diets abnormally low in "extrinsic factor" may have the same results.^{8, 27} Pregnancy, *Ankylostoma duodenale*, *Dibothriocephalus latus* and many other infestations and conditions have been incriminated as etiologic agents, but considerable doubt exists whether these are truly etiologic agents or merely precipitating factors in latent cases.

INCIDENCE

Although pernicious anemia occurs most frequently in Caucasians from the temperate regions,^{23 24} exceptions are so numerous that one cannot rely on nationality as a diagnostic aid. It is said to be unusual in the Negro, but we have recently shown⁵⁴ that its incidence has been much underestimated. The same is probably true for its rarity in Orientals, I myself having observed the disease in three Chinese. Seventy-five per cent of the cases occur between the forty-fifth and seventy-fifth years, but the age range is extreme. The occurrence in young children is debatable, though an occasional case is reported. Our youngest proved case was in a girl of seventeen.⁵⁵ We have noted a progressive increase in the rate per 100,000 beginning with 0.5 in the decade between ages ten and nineteen and reaching 553 in the decade between ages seventy and seventy-nine. There is a falling off of the rate above this but this falling off is probably more apparent than real (Tabulation)

TABULATION

INCIDENCE OF PERNICIOUS ANEMIA ACCORDING TO AGE

Age Group	Rate per 100 000
10-19	0.5
20-29	4.5
30-39	21.0
40-49	66.0
50-59	157.0
60-69	310.0
70-79	553.0
80-89	191.0

In our experience males and females have been about equally affected (495 males and 505 females)

Heredity is not of great significance, yet there is a distinct familial incidence, about 18 per cent of the patients²⁴ having relatives with the disease. Five proven cases in one generation,⁵⁶ occurrence in twins and in successive generations^{5 57} have all been reported, and I am aware of a family where three successive generations of daughters are affected. The finding of hypochromic anemia and achlorhydria in the families of patients with pernicious anemia is too frequent to be dismissed as pure coincidence.

Draper¹⁸ has described the pernicious anemia "type" as a

person having medium to tall build, broad face, large mandibular angle, short nose, long thin ears, wide, deep and short chest, wide subcostal angle, highly placed umbilicus, long abdomen, relatively wide pelvis and long lower extremities, eunuchoidal habitus, and feminine quality of the secondary sex characteristics in the male To this description we may add the broad spadelike hand and the usually massive bony structure, as well as the light eyes and light hair, which turns gray at an early age²⁴

SYMPTOMS

The symptoms of pernicious anemia usually appear so slowly that the patient cannot date the onset of the illness or its first manifestation with any exactitude For the most part the symptoms may be divided into four groups (1) general complaints, (2) those referable to the cardiovascular system, (3) those to the gastro-intestinal tract, and (4) to the nervous system This arbitrary division, though highly artificial since close interrelation and interdependence exists among the expressions of the disease, is justified by convenience for descriptive purposes

General Complaints

Most frequent complaints are *weakness* and a *sense of being unwell*—one or both of these being present in almost every case The degree of weakness is variable and may be so mild as to manifest itself only as slight lassitude or may be severe enough to cause total disability When extreme, the slightest exertion becomes impossible—the profound “languor” of which Addison spoke almost a hundred years ago With the weakness go also the symptoms due to the anoxia of the central nervous system such as faintness, dizziness, inability to concentrate, loss of memory, ringing in the ears, spots before the eyes, occasional blurring of vision and a sense of coldness As a rule the development of the general symptoms parallels the fall in the hemoglobin level

Cardiovascular Symptoms

The symptoms referable to the cardiovascular system follow even more closely the level of the blood Few cardiovascular manifestations are noted while the hemoglobin is above 50 per cent (8 gm), and in the slowly developing cases the paucity of complaints even with the hemoglobin level at 20 per cent (3 to

4 gm) or less is astonishing. It is to be remembered in this connection that it is the hemoglobin and not the red cell level that is of importance here since the individual cells contain more than their normal complement of hemoglobin and this determines the oxygen carrying capacity of the blood.

Dyspnea, appearing at first only after exertion and later with increasing ease, occurs in the majority of patients by the time they present themselves for examination.

Edema is the second most important symptom and depends for its development on cardiac dilatation and subsequent relative failure, on tissue anoxia, on lowered blood proteins, and the anemia itself. It is usually confined to the legs but may be more extensive.

Palpitation is almost as frequent a complaint as dyspnea, and is at first also noted particularly after exertion, though occasionally there is a constant awareness of the heart "pounding" even when lying down. With severe anemia, especially in the presence of changes in the coronary vessels, such as arteriosclerosis, where the blood supply of the heart muscle is already impaired, angina pectoris may be a complication.⁶³ With the amelioration of the anemia the pain disappears in most instances.

Gastro intestinal Symptoms

Most prominent among the gastro-intestinal symptoms is the *loss of appetite*. This may vary from a mild distaste for certain foods to anorexia so marked that little besides milk and cereals are eaten. To aggravate matters, the most essential food substances are the first ones eliminated. Dairy products, cereals and starches constitute the diet in the average case. Aversion to meat is so common as to bear special mention, the usual reason given being the "inability to digest it" and the "loss of taste for it." Frequently much patience and persuasion are required to re-educate the patient to eat a balanced diet, and meat in particular, even after the therapeutically induced remission.

Epigastric distress—usually described as "pains in the stomach"—and nausea and vomiting are the symptoms next in importance. Diarrhea is one of the "text-book" symptoms, but in our experience occurs in no more than a tenth of the cases, while alternating diarrhea and constipation is seen only in about 5 per cent. We have, on the contrary, found *constipation* to be the rule, occurring in well over half the cases.

The intensity of gastro-intestinal complaints roughly parallels the tongue changes, since in general the more extensive the atrophy of the tongue the more marked the atrophy of the upper gastro-intestinal mucosa^{33, 38, 52} The *tongue symptoms* in turn follow the atrophic changes seen in the papillae Varying degrees of tongue changes occur in almost all cases but tongue symptoms will be volunteered by only about a fourth of the patients They are variously described as "burning," "smarting," the sensation of "acid" on the tongue, or as intolerance to sour, salty, hot and occasionally rough foods Sometimes these sensations extend to the oral mucous membranes and the gums, leading to the mistaken diagnosis of "oral sepsis" with subsequent extraction of the teeth Many patients date their symptoms to the time the teeth were pulled, little realizing the cause-and-effect relationship

The emphasis on the preservation of the body tissues, persisting since Addison's time, has made us lose sight of the fact that great changes in weight occur We have found *weight loss* in almost every case during relapse and it was one of the presenting complaints in fully 60 per cent Even more striking than the history of weight loss is the remarkable gain in weight after therapy is begun This gain in the average case amounts to from 10 to 25 per cent of the body weight^{34, 64}

Symptoms Referable to the Nervous System

Symptoms referable to the nervous system occur in four out of five cases Earliest and most common complaints are "*tingling*" and/or "*numbness*" of the finger tips, present bilaterally and usually symmetrically The characteristic way in which patients describe this is by gently rubbing the thumb over the other fingers in rotation to indicate the site of involvement The lower extremity is usually affected subsequently At first the toes become numb, then there is a gradual extension upward with an increasing feeling of *coldness* Still later the leg becomes unsteady and there are peculiar subjective sensations variously described as walking "on air," "on clouds," "on pillows," "on rubber," and so on In later stages there may be an awareness of staggering and the feeling of "walking as if drunk"

The coldness and numbness may in time involve all the extremities and the entire trunk, though the upper arms and thorax are usually spared Walking, due to the loss of position sense

and the spasticity of the lower extremities, by this time has become impossible. Responsible for the symptoms are the degeneration of the posterior columns of the spinal cord carrying primarily proprioceptive and joint position sensations. When degenerative changes in the posterior columns dominate, spasticity is not a remarkable feature, on the other hand, when the dominant degeneration is in the lateral columns, spasticity is foremost. Stiffness and/or numbness leading to *difficulties in walking* are among the outstanding symptoms, being present in a mild form in about half and in a severe form in about a quarter of the cases. *Genito-urinary involvement*, manifesting itself particularly in bladder incontinence and decreased sexual desire in the male, is not uncommon. *Rectal incontinence*, frequently accompanying that of the bladder together with trophic changes, predispose to complications which unfavorably affect prognosis.

SIGNS

The common, though by no means constant, anthropological features found in patients with pernicious anemia have already been mentioned. There are a few other signs which are the rule but here again exceptions are numerous. *Pallor*, especially of the mucous membranes, is most frequent and varies with the degree of anemia. *Jaundice*, varying from a faint trace, visible only in the sclerae (icterus index 8 or 10), to frank jaundice (icterus index 25 or 30) appears in inverse proportion to the anemia. It imparts a yellowish cast to the skin, so often and so incorrectly referred to as "lemon-yellow" pallor. Rarely jaundice may be even more marked, but this most frequently occurs in complicated cases, cases with gallbladder or liver disease.⁷

The importance of the tongue as a diagnostic aid cannot be overemphasized, notwithstanding the fact that deviations from the typical *smooth tongue* are many. The completely bald, shiny, glistening tongue with all its papillae completely atrophied occurs in no more than 15 to 20 per cent of the cases—and when it does occur, unless complicated by dietary deficiencies, it is not "beefy red" but rather a pale, bloodless, orange-red ("veal-like"). The absence of a "coat" from the tongue has been the least variable and the most important sign. A coated tongue is sometimes seen but these exceptions are so infrequent as to lead to little confusion, and help but to emphasize the fact that pernicious anemia is indeed a *disease of exceptions*.

Changes in the heart are those secondary to the anemia, and as such vary with its severity. Dilatation is the rule and is best observed in the roentgenographic silhouette, which shows progressive shrinkage with improvement in the blood. Soft *hemic murmurs* appear when the hemoglobin falls below 50 per cent. They are usually systolic in time and are confined to the apical and pulmonary areas at first, but with the progression of the anemia may be heard over the entire precordium and in diastole as well. The presence of murmurs may lead to a mistaken diagnosis of heart disease, as we have had occasion to point out elsewhere.⁵³ A lowering of the blood pressure, usually not marked, is the rule, and is more pronounced in the systolic reading than in the diastolic. The electrocardiographic changes are non-specific and manifest themselves most commonly as low voltage, low or inverted T's, and lowered S-T segments.

Demonstrable *enlargement of the liver* is present in a fourth of the cases and it is not unusual to palpate the lower border 6 to 8 cm below the costal margin. The liver edge in these cases is firm, sharply demarcated, and nontender. *Splenomegaly* of sufficient magnitude to make the spleen palpable is only found in from 10 to 20 per cent of the cases. This may be quite marked at times, the lower border reaching 8 or even 10 cm below the costal margin. Shrinkage of both the liver and spleen follow induced remission. The persistence of splenomegaly in a treated case indicates a complication,⁹ but it is not unusual to find some residual liver enlargement.

Some *edema of the legs* is seen in almost every case with a hemoglobin level below 50 per cent (7.5 to 8 gm). It becomes marked in only 10 to 15 per cent of cases, and may be very extensive at times, manifesting itself on rare occasions as generalized anasarca. When this occurs, the prognosis becomes extremely grave.

Neurological signs most commonly encountered are the *loss of vibration sensation* in the lower extremities, *changes in deep reflexes*, the appearance of pathological reflexes, *loss of position sense*, and the appearance of a positive *Romberg sign*.⁵⁴ The earliest change is a quantitative diminution in vibration sensation at the level of the ankle. Gradually this spreads upwards and may reach the thoracic level with complete loss of vibration sense below. The deep reflexes (knee and ankle jerks) will be either hyperactive or hypoactive depending on whether the

posterior or lateral columns dominate. More extensive involvement of the posterior columns will lead to hypoactive deep reflexes while more severe lateral column damage will lead to hyperactivity. The former occurs twice as frequently as the latter. The appearance of pathological reflexes also depends on disproportionate lateral column degeneration.

Gait difficulties are essentially of two kinds: those depending on the loss of position sensation and hypotonicity and manifesting themselves as inability to walk in the dark, and as having a positive Romberg sign, and those due to spasticity and manifesting themselves in the typical scissors gait. Far more common than pure examples of either are combinations with one or the other type dominating.

Occasionally involvement of the cranial nerves is encountered the *loss of the sense of taste and smell* being the most common. Visual difficulties occur at times but are more usually due to hemorrhages in the fundi than to optic nerve changes.³⁷

A dulling of the sensoria secondary to the anemia of the brain is extremely common, and its significance lies in the fact that the anoxic changes may at times be irreversible. *Psychotic manifestations*³⁰ may even lead to the mistaken diagnosis of psychiatric disease. Because these patients usually have in addition the complicating urinary and fecal incontinence, the trophic skin changes, and decubitus ulcers, their prognosis is as a rule very poor.

LABORATORY FINDINGS

Most pertinent of laboratory findings in pernicious anemia are those in the blood. The degree of *anemia* is extremely variable. In cases showing neurological changes primarily the anemia may be so insignificant as to cause diagnostic difficulties,⁴⁹⁻⁵² or the count may go to incredibly low levels, the writer having seen the red cell count as low as 340,000. Characteristically the blood shows an *anemia*, *leukopenia*, *granulopenia* and *thrombocytopenia*.

The changes in the red cells may be considered pathognomonic and are characterized by *macrocytosis*, the large cells being ovoid in shape and, because of increased thickness, seem more highly colored than normal, with the resultant appearance of "*hyperchromia*." Macrocytosis is the earliest change and may be found even with red cell levels at four million. As the ane-

mia progresses the macrocytosis becomes more pronounced and at about a two and half million level *anisocytosis* and *poikilocytosis* appear. With progression of anemia these changes become more and more extreme. Rarely, when iron deficiency complicates the picture, the macrocytosis may be absent but the other changes are nevertheless present.

The presence of a leukocytosis before therapy is usually indicative of complications. Accounting for the leukopenia is not only the depression in granulocytes but also in lymphocytes. There is a right shift of the neutrophils with mature forms dominating, and many of the cells showing multiple lobulations of their nuclei.³⁵ The white cell count averages between 5000 and 6000 but drops sometimes to 1000 or 2000. Platelets are diminished in almost all cases,⁴⁴ but the diminution is rarely of such magnitude as to lead to clinical symptoms.

The second most informative laboratory test is the analysis of the gastric contents which, with extremely rare exceptions,^{22, 48} shows an *achlorhydria* and *achylia*. The exceptions to this rule are so few as to make one discredit the diagnosis of pernicious anemia without very substantial additional proof. The *icterus index* is elevated⁴¹ from 10 to 20 and on rare occasions may even rise over 30 in uncomplicated cases. Urobilinogen in the urine is also increased.²⁰

The determination of the *reticulocyte count* for practical purposes is unimportant, but is of aid in determining the potency of liver extract, and may be of value when liver is employed in a therapeutic test. In untreated cases the reticulocytes vary between 0 and 5 per cent, and start to rise about two days after the beginning of therapy. The reticulocytes reach a peak, whose magnitude is inversely proportional to the level of the original count,³² in five to seven days, on intramuscular liver therapy (40 per cent starting at one million, 20 per cent at two million, 10 per cent at three million). *Red cell increase* begins simultaneously with reticulocyte response and also rises at a rate inversely proportional to the original erythrocyte level.⁴⁶ The simplest way of calculating the expected daily rise is to divide the difference between the original and ideal red cell levels by 60 since regardless of the original blood level the normal count will be reached in about eight weeks.

The finding *sine qua non* is the *megaloblastosis* of the bone marrow.¹⁷ This must be present in every case in which the his-

tory, physical finding, neurological changes without anemia, or the presence of free hydrochloric acid makes the diagnosis questionable

CONCOMITANT DISEASES

Although individuals who have pernicious anemia may develop the same complicating diseases as others in similar age groups, there are certain illnesses that apparently occur with increased, while others with decreased, frequency. *Peptic ulcer* is said not to occur,⁵⁰ and explanation for this may be found in the achlorhydria and the emotional makeup. *Tuberculosis* is also said to be rare,⁵⁵ though roentgenographic evidence of primary infection is seen frequently. We have seen active tuberculosis in patients with pernicious anemia, though, considering the increased susceptibility, the incidence should be greater. Prominent among other complicating conditions are *arthritis*, *diabetes mellitus*⁵⁶ and *asthma*.

Thyrototoxicosis, in our experience, has shown an unexpectedly high incidence, considering the fact that it is supposed to occur in an entirely different age group and in individuals of different constitutional predispositions.^{4, 47} Thyrototoxicosis may precede or develop during the course of pernicious anemia. When the anemia develops after thyroidectomy in these cases it is not the macrocytic anemia occasionally encountered in the course of myxedema, but fulfills the strict diagnostic criteria of pernicious anemia, is accompanied by an elevated basal metabolism, and responds specifically to the administration of liver extract without additional thyroid.

Gallbladder disease also shows a significantly increased⁷⁰ incidence,⁷ which may be secondary to the increased pigment metabolism.

The termination of pernicious anemia in *carcinoma of the stomach* has been emphasized in the literature, metaplasia of the atrophic gastric mucosa with polyp formation and carcinomatous degeneration being postulated as the cause.^{23, 62} Considering the commonness of carcinoma of the stomach and the overlapping of the age groups in which both conditions are found, one may well question the validity of the emphasis placed on the relationship of the two diseases. In a large series of cases followed over a long period of time, I have been unimpressed by the frequency of stomach carcinoma.

DIAGNOSIS

The diagnosis of pernicious anemia is very easy when there are changes in the blood, the nervous system and the gastro-intestinal tract. Diagnostic difficulties are most likely to be encountered when a single symptom is disproportionately prominent and the others are either absent or insignificant. Thus a patient having only anemia might be suspected of *cardiovascular disease* because of the symptoms—a suspicion confirmed by the hemic murmurs, the occasional splenomegaly, and the fever.⁵³ Patients complaining of anorexia, nausea, vomiting and epigastric pains may be assumed to have *gastro-intestinal disease* especially when weight loss and change in bowel habits are added to the symptoms. *Primary neurological disease* is often diagnosed when the anemia is mild or absent, a circumstance by no means uncommon since there is usually a reciprocal relation between the severity of the anemia and the nervous system involvement.^{60, 62, 67}

At first glance the appearance of the patient may suggest *nephritis* or *myxedema*, but these diseases can be easily differentiated clinically. Hematologically, sprue,¹⁰ fish-tapeworm infestation and carcinoma of the stomach are said to lead to confusion most frequently, but in our experience *aleukemic leukemia*, *myelophthisic anemia*, and *aplastic anemia* have caused the greatest diagnostic difficulties.

The rules to follow in attempting to diagnose pernicious anemia are

- 1 Suspect pernicious anemia in every case where no *obvious* cause for the anemia exists, where vague abdominal discomfort is associated with anemia, or where paresthesias of the extremities coexist with anemia or gastro-intestinal symptoms. At this stage pernicious anemia is suspected.

- 2 Examine the patient, looking in particular for the anthropological features described above, the gray hair, light eyes, pallor, scleral icterus, atrophy of the tongue papillae, the presence or absence of lymphadenopathy, hepatomegaly and splenomegaly. Neurologically, changes in the deep reflexes, a positive Romberg sign and loss of vibration sensation are looked for. Should confirmatory information be supplied by the examination, a tentative diagnosis of pernicious anemia may be made.

- 3 If the blood presents anemia with a high color index, leukopenia, thrombocytopenia and granulopenia, if the red cells

are large and oval, and are well filled with hemoglobin, and in addition show alteration in size and shape (not at high red cell level¹), and if in addition multilobed polymorphonuclear leukocytes are seen, the probable diagnosis of pernicious anemia may be made, and liver therapy begun lest the patient be jeopardized by waiting

4 While awaiting therapeutic response (five to eight days) the following confirmatory tests should be performed

- (a) Icterus index or Van den Bergh determination
- (b) Urinary urobilinogen determinations
(These must be performed within twenty-four to forty-eight hours since their values drop markedly thereafter)
- (c) Analysis of the gastric contents following histamine stimulation (twenty to thirty minutes after the administration of 0.1 mg of histamine hydrochloride per 10 kg body weight subcutaneously)
- (d) Stool examination for occult blood and parasites or their ova

If the bilirubin of the blood and urobilinogen of the urine are increased, no free acid is found in the gastric secretions, and neither blood nor parasites are present in the stool, a positive diagnosis of pernicious anemia may be made

Occasionally one may wish to hasten making a positive diagnosis or may wish to confirm it with examination of the marrow whose changes are pathognomonic¹⁷ But even in cases thus diagnosed, the above described tests should be performed to rule out a pernicious anemia secondary to gastric neoplasm, fish tapeworm, or other causes

TREATMENT

Liver extract is specific for the treatment of pernicious anemia. Only general rules can be formulated as to the mode of its administration, since individualization of the patient¹⁸ is as important, or is even more important, than in other diseases where specific therapeutic agents are known. One unit* of liver extract per day on the average is required for maintenance, but extreme variations are encountered

Cases may roughly be divided into two groups, depending on the presence or absence of neurological signs and symptoms

* A unit is defined as the amount of liver which when given in a uniform daily dose in a case of pernicious anemia in relapse will elicit a satisfactory red cell and reticulocyte response

Patients without neurological complications should get an average of 15 units of liver extract intramuscularly three times a week for the first two weeks, twice a week for the next two weeks, and weekly for the next month. By the end of this time (eight weeks) the blood has reached a normal level. From here on doses of 15 to 30 units of liver extract can be given anywhere from once a week to once every four to six weeks depending on individual requirement. The best plan is to "wean" the patient by cutting the frequency of injections by a week every two to three months. There is little merit in examining the blood at intervals less than two to three months, since the patient's sense of well being, the paucity of complaints, the color, and the appearance of the tongue are sufficiently good indices of adequate therapy. Once the maintenance dose is established there need be little deviation from it unless complications (infections, bleeding, pregnancy, and so forth) occur. The need for liver increases considerably when complications are present and allowance must be made for this by increasing either the dose or the frequency of administration, or both. The site of injection depends on preference. We have found the upper portion of the deltoid muscle the site of choice, here amounts up to 3 cc are tolerated without discomfort.

Treatment in *cases complicated by neurological symptoms* is much more intensive. In general, 20 to 30 units are given daily for the first two weeks, three times a week for four to six weeks, then twice weekly for another four to six weeks, and finally weekly until all neurological symptoms shall have disappeared, or until no further improvement is thought possible. Such intensive treatment should be continued for at least two years before one may assume that no further improvement is possible. Improvement in neurological symptoms is manifested by a return of normal sensation to the uppermost regions involved, with a gradual progression of this process downward. Objectively the improvement can best be followed in patients showing changes in vibration sensation, in whom the return of the sensation to lower and lower levels can be traced. It has been my impression that the cruder liver extracts (i.e., less potent extracts—not to be confused with diluted extracts) are more efficacious in the cases showing neurological changes. We do not deem it necessary to combine vitamins with liver to achieve optimal results. Once maximal improvement in the neurological

symptoms is reached, the same process of "wearing" may be followed as described above, but it is seldom possible to reduce the liver to amounts comparable to those sufficient for purely hematological types without a recurrence of symptoms

The administration of *hydrochloric acid* routinely is unnecessary. We employ it only when gastro-intestinal complaints persist, or appear in spite of adequate liver therapy. Fifteen to 30 drops (Diluted Acid Hydrochloridi, U S P) in half glass of water is either sipped with or is taken after meals. It is interesting that this almost insignificant amount (when compared to the normal gastric secretion) should result in the almost constant and striking relief that follows its administration.

The administration of *iron*, in addition to the liver extract, becomes necessary only when a concomitant iron deficiency develops. When this occurs it is first noted three to four weeks after the beginning of liver therapy and manifests itself as a gradually increasing hemoglobin lag and the development of a progressively lower color index. The red cell count levels off at about 4 million, with the hemoglobin at 60 per cent (10 gm), and remains there until iron is given. With this both the red cells and the hemoglobin rise to normal levels.

Complicating or coexisting diseases are treated just as if the pernicious anemia were nonexistent, remembering only that additional amounts of liver may be necessary.

A disconcerting complication, which occurs at some time in almost 10 per cent of patients treated for long periods, is the appearance of allergic reactions. These vary in severity from mild itching to shock and collapse. Changing the brand of liver will often suffice to eliminate reactions. If this fails, desensitization may be tried by the administration of increasingly larger doses beginning with extremely small amounts (such as $\frac{1}{10}$ of a unit). Should this fail, two alternatives remain: the administration of oral instead of parenteral liver in the form of the liquid or dry extract, or the administration of stomach extract. Ordinarily certain practical objections exist which make the writer advise against the use of *oral extracts*. These may be summarized as follows: (1) eventual neglect of therapy due to lack of supervision, (2) greater cost, (3) greater difficulty in maintaining the blood at optimal level and (4) the development or progression of neurological signs and symptoms in spite of therapy.

Therapeutically, few diseases in the field of internal medicine are as satisfying to both the patient and his physician. The dramatic and spectacular improvement following the administration of liver is practically unequalled, and with the exception of the occasional inconvenience of liver injections, the patient continues with a normal life expectancy.

THE RH FACTOR*

I DAVIDSOHN, M.D., F.A.C.P.†

THE Rh factor is a property of human blood, the latest of a series of previously discovered blood factors. In order to understand the Rh factor, it will be necessary to review the other known properties of blood.

Since the discovery by Landsteiner of the first two blood factors, A and B, in 1901,¹ several additional factors have been discovered. Some are little known, others are known better but have assumed no importance in the practice of clinical medicine and surgery, though they are applied in the practice of legal medicine. This discussion will be concerned mainly with blood factors of interest to clinicians, especially in connection with blood transfusions.

HEMAGGLUTINATION AND HEMOLYSIS

The frequently tragic results of early attempts at blood transfusion were due mainly to lack of knowledge of two reactions that may occur when the blood of two individuals of different species, and often when blood of two individuals of the same species, is mixed. One of these reactions is *clumping* or *agglutination* of the red blood cells of one individual by serum or plasma of the other. This special form of agglutination is called *hemagglutination* to differentiate it from other forms like bacterial agglutination. The second reaction is *laking* or *lysis* of the red cells by serum or plasma and is called *hemolysis*. The latter phenomenon, though of greater importance in blood transfusion reactions, is more complex than hemagglutination and more difficult to demonstrate. As hemolysis does not occur in the absence of hemagglutination, this discussion will be limited

* From the Department of Pathology, Mount Sinai Hospital.

to the latter except when special circumstances will require mention of hemolysis

Two elements are essential for hemagglutination the red cells which are clumped, the *agglutnogen*, and a substance in the serum or plasma which brings about the clumping, the *agglutinin*. The injection of red cells (the antigen) of one animal species into another leads to the production of agglutinating antibodies or *hemagglutinins*. They clump specifically the blood cells of the injected species

In addition to these agglutinating antibodies produced by immunization, or *immune agglutinins*, another type of hemagglutinins, not due to previous immunization, has been known as *normal hemagglutinins*²

The agglutination of red cells of one species by the serum of another was not surprising in view of other differences between species. Very startling was the discovery by Landsteiner¹ of agglutination of red cells of one person by the serum of another, both of them normal and healthy. Here for the first time individual differences were observed in the blood of members of the same species, *isoagglutination*, as contrasted with *heteroagglutination* or agglutination in mixtures of blood of different species. Even after Landsteiner's discovery there were reports in the literature referring to isoagglutination as a pathologic phenomenon, a manifestation of disease, and various authors claimed it to be a specific diagnostic test for a variety of diseases. Later studies confirmed Landsteiner's concept of isoagglutination as a normal physiologic phenomenon

BLOOD GROUPS

In experiments which led to the discovery of blood groups Landsteiner studied the behavior of mixtures of serum and of red cells of various persons. He found from the behavior of these mixtures that people could be divided in three groups the largest group consisted of persons whose red cells were not clumped by serum of any other person, the red cells of a slightly smaller second group, and of a considerably smaller third group were clumped by certain serums. Landsteiner assumed the existence of two different agglutinable substances in the two last mentioned groups, factor A in the larger and factor B in the smaller group. He explained the failure of the red cells in the first mentioned, largest group to be clumped by the absence in

them of both of these factors and expressed it by the numeral "0." Later it became customary to refer to the "0" as a letter instead of a numeral

Corresponding to the factors in red cells there are agglutinins in the serum anti-A (also called "a" or α) reacts with factor A, and anti-B (also called "b" or β) reacts with factor B

Factor A and anti-A cannot be present in the blood of the same person, nor can B and anti-B, as this would not be compatible with life This is expressed in *Landsteiner's law*. Every person has in his serum agglutinins that react with the factor or factors absent in his red cells Persons of group A have anti-B isoagglutinins, persons of group B have anti-A agglutinins, and persons of group O have anti-A and anti-B agglutinins

To these three groups a fourth, very rare group was added when a small number of persons was found whose red cells were clumped by the serums of persons belonging to the other three groups It was shown that the red cells of this group contain both factors, A and B, and it became known as group AB The serum of these persons lacks both anti-A and anti-B and does not agglutinate cells of any blood group

Distribution of blood groups varies in different races. In the white population in this country, about 45 per cent belong to group O, about 40 per cent to A, about 11 per cent to B, and about 4 per cent to AB

APPLICATION OF THE DISCOVERY OF BLOOD GROUPS TO BLOOD TRANSFUSIONS

It would seem that Landsteiner's discovery of differences in the properties of the blood and of incompatibilities arising therefrom should have been followed immediately by the practical application of this knowledge to blood transfusion This is indeed the prevalent opinion, even among those who are especially interested in blood transfusion. Actually, a study of the literature of the first decade of this century reveals a gap of several years during which one fails to find any clear evidence of a practical application of the discovery of blood groups

Hektoen was the first to recommend in 1907³ the selection of compatible donors in order to avoid transfusion reactions His recommendation was that there be "selection of a donor whose corpuscles are not agglutinated by the serum of the recipient and whose serum does not agglutinate the corpuscles of

the latter [to avoid the danger of] erythrocytic agglutination within the vessels of the subject transfused" He suggested at the same time a simple procedure for cross-matching tests claiming that the actual isoagglutinative relation of the donor and the recipient is readily determinable Hektoen's fundamental contribution to the safety of blood transfusions by the practical application of the knowledge of blood groups to the selection of compatible donors has been generally overlooked

Landsteiner and Levine⁴ discovered in 1926 two additional blood factors, M and N About 30 per cent of the population have factor M, about 20 per cent have N, and the rest have both M and N, thus forming three types M, N, and MN The term "blood types" is used in contradistinction to the "blood groups" A, B, AB, and O The factors M and N play no part in relation to blood transfusions because there are no agglutinins against them in our blood normally, nor is a person of type N able to produce immune agglutinins against M when transfused with blood of type M or vice versa

DISCOVERY OF THE RH FACTOR

The Rh factor was discovered in 1940 by Landsteiner and Wiener⁵ Rabbits were injected with the blood of the rhesus monkey (*Macacus rhesus*) Following a series of injections their serum clumped the red cells of the monkey, as was to be expected, but also the red cells of about 85 per cent of human beings Landsteiner and Wiener accordingly assumed that there is a common antigenic factor in the blood of the rhesus monkey and of about 85 per cent of human beings The factor was designated as Rh to indicate its relation to the animal species. The 85 per cent who have the Rh factor in their blood are called *Rh-positive*, the remainder are *Rh-negative*

It was shown that the Rh factor is independent of the other blood factors It occurs with the same frequency in persons of all groups and types, and is not related to sex It differs from the factors A and B in several ways There are no normal agglutinins against it, i.e., Rh-negative persons do not have in their serum agglutinins capable of clumping the blood of Rh positive persons

Diamond⁶ observed anti-Rh agglutinins in a child with nephrosis without a history of previous transfusions, but such instances must be extremely rare Agglutinins capable of

clumping Rh-positive blood are due to immunization by the Rh factor and will be discussed later

The reference to factors A and B as blood properties is not entirely correct, because they are present not only in the blood but in tissues and in secretions, for instance saliva, of most persons of groups A, B, and AB. The Rh factor is found only in red blood cells. In both respects, in the absence of agglutinins against it, normally, and in its exclusive presence in red blood cells, the Rh factor is similar to the blood type factors M and N.

The rapidity with which the Rh factor became widely known is due to the fact that it helps to make understandable certain, previously unexplainable transfusion reactions, and that it has become the basis for a plausible hypothesis of the genesis of erythroblastosis foetalis.

COMMON ERRORS IN TYPING AND CROSSMATCHING

In the course of the years rules have been evolved governing the selection of safe donors for transfusions. The profession learned to recognize causes of errors and to guard against them in the typing of blood and in crossmatching tests. Some of these errors are due to the method of preparing reagents (typing serums, cell suspensions), some are due to the technic of the tests (temperature, speed of performance, bacterial contamination, and so forth), and some are due to inherent properties of the reagents (such as rouleaux formation, titer of agglutinins and irregular agglutinins). It is known that as a rule it is preferable to use donors of the same group as the patients, that the use of donors of group O (Moss IV) or so-called universal donors is to be restricted by various considerations which cannot be discussed in detail on this occasion. It has also been learned that crossmatching tests must be done before each transfusion.

The technic of transfusion has also been greatly improved, thus eliminating other sources of danger. The result of these advances has been that when a suitable donor was selected and when the transfusion was done according to established rules, there was good reason to expect that there would be no serious reaction.

THE RH FACTOR IN TRANSFUSION REACTIONS

In spite of all precautions, and in spite of using donors of the same groups as patients, instances of severe and even fatal trans-

fusion reactions* have been known to occur. In some such cases a subsequent recheck of typing and of crossmatching failed to reveal any evidence of incompatibility. There was no explanation for these tragedies. They had to be dismissed as unexplainable accidents. When the donor and recipient were of the same group the cases are referred to as *intragroup transfusion reactions*.

Although there was no satisfactory explanation and no known means of avoiding such reactions, accumulated experience brought out two facts: (1) most of these reactions occurred in recipients who had received previously one or several transfusions without any reaction or with mild reactions and then the last transfusion was followed by a severe, usually hemolytic and sometimes fatal reaction, and (2) a smaller number of instances in which the first transfusion was followed by a severe or even fatal hemolytic reaction. Here too an interesting phenomenon has been observed. The majority of these reactions following a first transfusion occurred in *pregnant women*, usually during delivery or soon after childbirth or abortion.

Levine and Stetson⁷ were the first to throw some light on the second type of these reactions when they reported in 1939 a hemolytic reaction in a woman who was given a transfusion following an abortion. The recipient and donor belonged to group O. Reexamination after the transfusion revealed the presence in the blood of the patient of an irregular agglutinin which clumped the blood of about 80 per cent of persons regardless of their blood group, even those of group O. Levine and Stetson suggested that the *irregular isoagglutinin* was the result of immunization of the patient in the course of pregnancy by an antigenic substance coming from the fetus. The substance was assumed to have been inherited by the fetus from the father and to have been transmitted from the fetus to the mother through the placenta. Later developments have shown the correctness of this ingenious hypothesis, although the discovery of the Rh factor was needed to furnish a complete explanation of the exact mechanism.

Shortly after the discovery of the Rh factor, Wiener and Peters⁸ studied three cases of hemolytic transfusion reactions in patients

* The most serious, so-called hemolytic reactions are characterized by hemoglobinemia, hemoglobinuria, icterus, oliguria with progressive azotemia, anuria, uremia and sometimes death.

who had received previously one or several transfusions without untoward manifestations. The recipients and donors were in the same group. An investigation of the serum of the recipients by means of an especially sensitive technic revealed the presence of an irregular agglutinin reacting with red cells of the donors and of about 80 per cent of persons, regardless of the blood group and including the usually inagglutinable group O. The irregular agglutinin in the patient was found to be similar to the agglutinin produced in rabbits by injection of rhesus blood. Both agglutinins clumped the cells of the same persons. The patients were shown to be Rh-negative, the donors whose blood was responsible for the reactions were Rh-positive and so were some of the donors whose blood was used in one or several of the previous transfusions.

Here was an obvious explanation of the transfusion reactions. The injection of Rh-positive blood into Rh-negative persons may be followed by development of anti-Rh agglutinins, just as it happened in the rabbits that were injected with rhesus blood.

There will be, of course, individual variations. Some Rh-negative persons will develop agglutinins after only one transfusion. Some will require several transfusions, and there may be persons who will not develop any demonstrable antibodies. After sensitization has taken place, the recipient and the donor, though of the same group, are not compatible any more as they had been before the recipient developed antibodies against the Rh factor.

The argument was clinched when Rh-negative recipients reacting unfavorably to transfusion of Rh-positive blood stood transfusions of Rh-negative blood without an untoward reaction and with the usual evidences of beneficial effects of successful transfusions. Thus the majority of severe transfusion reactions in recipients with a history of previous uneventful transfusions was explained by *Rh factor incompatibility*.

In some cases of such reactions, agglutinins against Rh-positive blood could not be detected in the serum of the recipient. Three possible explanations were offered⁹ for their absence: (1) the tests were done too soon and the agglutinins were neutralized by the injected Rh-positive blood and a repetition of the tests after varying intervals of time revealed their presence in some instances; (2) the tests were done too late after the transfusion and the agglutinins have disappeared, as it is known to happen in other immunizations, (3) demonstrable agglutinins may not have been present in the circulating blood even before the transfusion—they may have been attached to the cells of the reticulo-endothelial system or their titer may have been too low to be detected by the available methods. The third explanation was substantiated by actual experience. Patients who developed hemolytic reactions fol-

lowing transfusion were found to be Rh-negative but did not show anti-Rh agglutinins on repeated examinations. The donors were Rh-positive. Transfusions with Rh-negative blood were free of reactions, while further transfusions with Rh-positive were followed by severe reactions.

The hypothesis of Wiener and Peters, confirmed by a long series of reports, can be accepted at the present time as offering an explanation for a majority of previously unexplained intra-group transfusion reactions and as furnishing means of avoiding many of them.

The second group of severe hemolytic reactions following first transfusions, as was mentioned, have been observed to occur mainly in *pregnant women* during or soon after delivery or after abortion. The application of sensitization by the Rh factor to the previously quoted case reported by Levine and Stetson⁷ gave the clue for an explanation.¹⁰ An Rh-positive husband of an Rh-negative wife may transmit the Rh factor to the fetus. Antigenic substances containing the Rh factor may pass from the fetus through the placenta to the mother and stimulate in her the development of anti-Rh agglutinins. If the mother needs a transfusion, the natural procedure would seem to be to use the husband as a donor if he belongs to the suitable blood group. It is obvious from our present knowledge, however, that the husband may be the least suitable donor, even if he is of the same group as his wife. If the foregoing situation regarding the Rh factor prevails and his blood is transfused, the result may be similar to that following a transfusion of incompatible blood—a severe or even fatal hemolytic reaction. Even if another donor is used instead of the husband, the chances are four out of five that the donor is Rh-positive and the result will be similarly disastrous.

A study of the blood of women who have suffered such transfusion reactions, of donors whose blood was responsible for them, and of babies (whenever that was possible) confirmed the existence of this immunologic state of affairs in a sufficiently large number of cases to permit the conclusion that this explanation is applicable to most instances of such reactions.

The questions may be asked at this point: *Why is it that cross-matching tests prior to these transfusions done with the usual methods failed to show incompatibility? Why did repetition of*

crossmatching tests, after the reactions had occurred, fail to reveal incompatibility.⁷ The answer is that testing for the Rh factor and for anti-Rh agglutinins requires a special technic, more sensitive and delicate than tests for the usual isoagglutinins. The isoagglutinins anti-A and anti-B, which are used to detect the four blood groups, A, B, AB and O, have as a rule a higher titer than the anti-Rh agglutinins. They react within a wide range of temperature, from icebox temperature where the titer is at its peak, declining slightly through room and body temperature, and remaining detectable in most instances even at temperatures close to 50° C. Anti-Rh agglutinins react, as a rule, best at body temperature, and lose their strength rapidly with changes of temperature in either direction, so that at room temperature, at which the usual blood grouping and crossmatching tests are done, Rh-agglutination is in most instances difficult to detect or is even absent.

Rare instances have been reported⁸ of anti-Rh agglutinins reacting better, or exclusively, at icebox temperature. The usual grouping and crossmatching tests are done on slides, Rh agglutination has to be carried in test tubes and requires prolonged sedimentation or centrifugation, which are known to favor all agglutination reactions. Thus it is apparent that the reason for the failure to discover Rh incompatibility prior to the introduction of the special sensitive technic was due to the usual methods of doing grouping and matching tests on slides and at room temperature, while Rh agglutination requires that the tests be done in test tubes at 37° C., and that the reaction be reinforced by fairly long incubation or by centrifugation.

THE RH FACTOR AND ERYTHROBLASTOSIS FOETALIS

After Levine had explained the transfusion reactions in pregnant women as due to sensitization of mothers by antigenic substances passing through the placenta from the fetuses, it was logical to consider the further consequences of this unique immunologic situation.¹¹ The placenta is a two-way road. If antigenic substances pass through it from the fetus and cause the production of antibodies in the mother with the resulting potential danger to her, the passage of these antibodies from the mother through the placenta may have a damaging effect on the fetus. This line of thought had been taken up in the past by several investigators. Darrow¹² came closest to what seems to be the solution of the problem when she incriminated chemical and antigenic differences in the hemoglobin of the fetus and mother as the responsible agents. She reasoned correctly that

the mother may be sensitized by the hemoglobin of the fetus, and that the antibodies thus produced may damage the child. The hypothesis was well conceived but lacked confirmation.

Levine's hypothesis substituted the Rh factor in the red cells of the fetus for the hemoglobin. Rh antibodies passing from the mother to the fetus damage its erythropoietic system and produce a hemolytic anemia and the other manifestations of the disease known as erythroblastosis foetalis.

Levine and his associates¹³ checked this hypothesis by the simple means of comparing the incidence of the Rh factor in mothers of babies with erythroblastosis with that in the general population. Levine found about 90 per cent of them Rh-negative, while the incidence of Rh-negatives in controls was about 15 per cent. The husbands of these women and the babies afflicted with the disease were found to be Rh-positive in almost 100 per cent of cases, while the incidence of this property in the general population is about 85 per cent. Statistical data published by others¹⁴ are in close agreement with Levine's.

It was found that many mothers of babies with erythroblastosis have anti-Rh agglutinins reacting with the blood of the baby. The serum of these mothers became the most important reagent for the detection of the Rh factor.

Two pertinent questions present themselves at this point. If erythroblastosis is based on the presence of the serologic condition of an Rh-positive father, an Rh-negative mother and an Rh-positive baby, *how can this hypothesis be reconciled with the finding of about 10 per cent of Rh-positive mothers in Levine's own series and with similar findings by other authors?* This can be answered by calling attention to the fact that fetal erythroblastosis is not a disease due to one specific cause, as for instance typhoid fever is due to the typhoid bacillus. It is in keeping with known facts about the disease that any agent capable of damaging the blood of the fetus and of producing a hemolytic anemia may start the chain of events that eventually produce the clinical syndrome known as erythroblastosis foetalis. Thus Rh antibodies are not the only agents capable of producing the disease, though apparently they are in most instances responsible. It is likely that various diseases of the mother may cause transmission of hemolytic substances to the fetus through the placenta and produce a result similar to or indistinguishable from fetal erythroblastosis. It is known that syphilis may do it. It is possible that other factors, thus far unknown, are operative.

The existence of antigenically differing fractions of the Rh factor has been demonstrated^{9, 15, 16, 17} It is theroretically possible, though still to be proved, that a mother and her child may both be Rh positive but have different antigenic fractions. The mother may lack a fraction possessed by the child and thus become sensitized. It is therefore not necessary to construe the finding of Rh-positive mothers or of Rh-negative fathers or babies as in any way detracting from the validity of Levine's hypothesis The fact is that the hypothesis is applicable in about 90 per cent of the cases, and this is as good a corroboration as any hypothesis may be expected to furnish

The second question is *Why is erythroblastosis foetalis such a rare disease?* The question is justified by the discrepancy between the relative frequency of the combination of Rh-positive husband and Rh-negative wife (calculated to occur in about 13 per cent of marriages), and the reported rarity of the disease (quoted in statistics to be from 0.1 to 0.2 per cent of births). This contradiction is more apparent than real and it can be explained by a consideration of various factors which are involved in the mechanism of the genesis of the disease.

In the first place, an Rh-positive father does not have to transmit the Rh factor to his child The Rh factor of a person, his phenotype, is the result of inheritance from his parents He may inherit the Rh-positive property from both parents Then the formula of his blood is Rh Rh and he is homozygous, or he may inherit from one parent the Rh-positive property and from the other parent the Rh-negative property (designated as rh), and then his formula is Rh rh and he is heterozygous There is no test available for distinction of homozygous persons from heterozygous The child of a homozygous Rh-positive father will always be Rh-positive, while the child of a heterozygous father may be either Rh-positive or Rh-negative This mechanism cuts considerably the incidence of Rh-positiveness in children Kariher¹⁸ reported recently erythroblastosis in one of twins who was Rh-positive, while the Rh-negative twin remained well

The next point has to do with the production of Rh antibodies in the Rh-negative mother of an Rh-positive child It does not follow that in each case of such a combination the mother must produce Rh-antibodies It is possible that passage from the fetus to the mother must be facilitated by an abnormally increased permeability of the placental barrier in order to permit the entrance of sufficiently large amounts of antigenic substances We know from experimental investigations in man and animals that active immunization depends on such quantitative factors This consideration is supported strongly by clinical evidence Erythroblastosis

foetalis is extremely rare in the first child. As a rule, one or more normal children precede the birth of a child with the disease. This may be interpreted as indicative of the need of several successive immunizations before the antibodies in the blood of the mother reach the level necessary to exert the destructive action in the child. In this connection it may be added that women may differ in ability to produce antibodies, as is known to occur in infectious diseases and in animal experiments.

The previously mentioned fact that the incidence of erythroblastosis increases with the number of pregnancies, suggests another factor contributing to the rarity of the disease—the tendency to limit the number of children in modern marriages. In Javert's series,¹⁹ multiparity was associated with erythroblastosis in 92 per cent of the mothers. The disease is rare in primiparous women. It is interesting that in a case reported by Diamond⁸ the mother of a first-born child with erythroblastosis had received eight transfusions prior to pregnancy. The last two transfusions were followed by hemolytic reactions.

After the antibodies have been produced in the mother in sufficient strength they have to pass to the baby. Here again the *permeability* of the placenta enters into the picture. It is possible that it has to be abnormally increased and the permeability in the direction from the mother to the baby may be of a different nature than in the opposite direction. Both may have to be increased to permit the working of the postulated mechanism, thus again limiting the frequency of the disease.

Finally, recent reports suggest that erythroblastosis may occur in *mild form*, (sometimes as a relatively mild hemolytic anemia) and that it may not infrequently escape recognition. This point will be taken up later in greater detail.

The factors just enumerated seem to me to be sufficient to account for the apparent discrepancy between the true incidence of the disease and the number of marriages between Rh-positive men and Rh-negative women.

Although Levine's hypothesis is strongly supported by statistical evidence, it is possible to conceive certain further corroborative observations.

1. An Rh-negative wife of an Rh-positive husband, mother of one or several children with erythroblastosis, may marry again, this time an Rh-negative man, and have with him healthy Rh-negative children.

2. An Rh-negative mother of Rh-positive children with erythroblastosis, wife of an Rh-positive man, may consent to arti-

ficial insemination from an Rh-negative donor and conceive normal Rh-negative children

3 An Rh-negative wife of an Rh-positive man may give birth to twins, one Rh-negative free of disease, the other Rh-positive suffering from erythroblastosis. The husband has to be, in such a case, heterozygous. The previously mentioned report of Kariher¹⁹ is the first instance of this type.

The Development of Manifestations of Erythroblastosis Foetalis

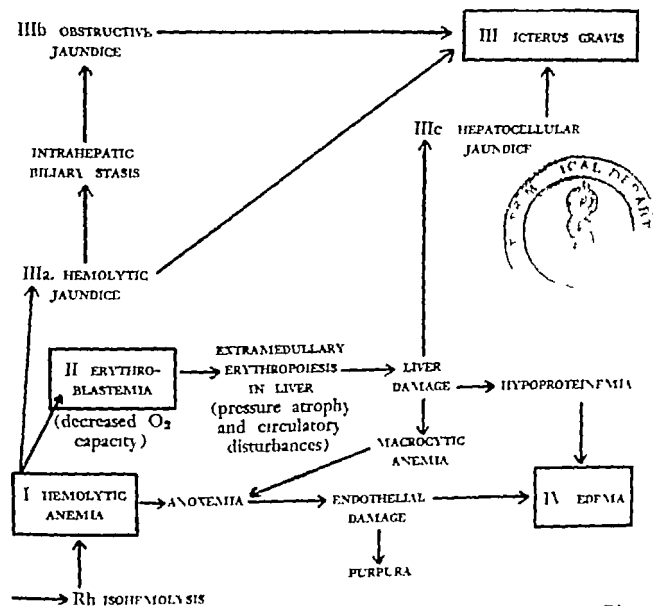

If it is agreed that Rh antibodies may produce hemolytic anemia in the fetus, how is the development of the other manifestations of the syndrome known as erythroblastosis foetalis to be explained? This is a question worthy of consideration in view of the heterogeneous manifestations of the disease of which the four most important ones are *hemolytic anemia*, *erythroblastemia*, *icterus gravis*, and *congenital hydrops*.

Figure 36 shows how these manifestations follow each other, step by step, in logical order. The results of hemolytic anemia are threefold: (1) *Anoxemia* (anemic anoxia) occurs as a result of a reduction of the oxygen-carrying capacity of the blood. (2) *Hemolytic icterus* develops from the destruction of blood and as a result of the presence of excessive amounts of components needed for formation of bile. This is an exaggeration of the normal tendency to jaundice in the newborn (*icterus neonatorum*). It differs from it by being present at birth (*icteric vernix caseosa*) or by appearing during the first day of life, while *icterus neonatorum* does not, as a rule, become manifest before the end of the second day. (3) *Erythroblastemia*, an abnormally increased number of nucleated red blood cells in the circulation, is a response of the bone marrow to hemolysis. The bone marrow of the newborn and of the child is known to respond to stimuli more intensely, quantitatively as well as qualitatively, than the marrow of the adult. It is known that nucleated red cells have a lower oxygen-carrying capacity than mature cells. A large number of such cells in the circulation adds to the anoxemia.

Each of the three results of hemolytic anemia leads to further developments, and these in turn are followed by others. The changes are frequently interconnected with one another. I hope that the chart (Fig. 36) will help to clarify this seeming maze.

In response to the anemia, *foci of erythropoiesis* develop in different organs. For the purpose of this discussion the most important are the *changes in the liver*. One finds frequently large masses of immature erythroblasts in the sinusoids compressing the liver parenchyma. In addition liver cells are frequently gorged with

hemosiderin and finally damage to the endothelium of the bile capillaries by the anemic anoxia adds the third factor leading to interference with normal hepatic function. Damaged liver function manifests itself in three ways, as shown in Figure 36. One is *hypoproteinemia*, the formation of blood proteins being one of the main

PRINCIPLE Rh positive husband of Rh negative woman transmits the Rh factor to the fetus. Rh antigenic substances pass from Rh positive fetus through placenta and produce in mother Rh antibodies. The latter pass from mother to fetus through placenta, act in the fetus as hemolytic agents, and start the sequence of interlocking pathologic changes as presented in this chart.

Fig. 36—Pathogenesis of erythroblastosis foetalis

functions of the liver. Hypoproteinemia, in turn, leads to *edema*, which has the oldest history of all manifestations of erythroblastosis, having been known for centuries as congenital hydrops. The other result of hepatic damage is a *hepato-cellular type of jaundice*, which tends to intensify the previously mentioned hemolytic jaundice. Liver damage is known to be associated with *macrocytosis*, which

is present in erythroblastosis²⁰ Macrocytes are less efficient carriers of oxygen than normocytes and so contribute to the anoxemia, similar to erythroblasts

The anoxemia, the development of which we have traced from at least three sources, hemolytic anemia, erythroblastemia, and macrocytosis, results in *endothelial damage*, which is responsible for three types of changes. It causes edema, thus acting synergistically with the hypoproteinemia. Endothelial damage explains the purpura, an occasional complication of the disease. Finally, the damage to the endothelial lining of biliary capillaries together with the stasis of bile due to hemolytic jaundice contribute to formation of bile plugs in the liver which lead to intrahepatic biliary obstruction and to obstructive jaundice. Thus we have now the third element in the formation of the severe jaundice of erythroblastosis, the *icterus gravis*.

The chart makes it clear, I hope, why *edema* is the most serious manifestation of erythroblastosis and the least frequently reversible. That is the reason why infants with generalized congenital hydrops recover so rarely. In Javert's¹⁹ series the mortality was 100 per cent. Anemia and erythroblastemia are usually most pronounced in this form, jaundice may be masked by edema.

Icterus gravis is next in seriousness, with a mortality of 54 per cent (Javert). It is likely that its seriousness and the chances of recovery may depend on the associated liver damage. It is justifiable to conclude from the chart and in keeping with clinical experience, that hemolytic anemia may be present as the only manifestation of the disease, with or without excessive erythroblastemia. If mild, it may be overlooked entirely or it may not be interpreted as a manifestation of erythroblastosis. The suggestion has been made that the disease would be better called hemolytic disease of the newborn²¹. The suggestion has much in its favor, as hemolytic anemia is the basic change in the disease and erythroblastemia is a less significant finding.

There is a tendency in recent publications to consider every case of *hemolytic anemia of the newborn*, even when it is moderate or mild, and even without erythroblastemia or jaundice, a manifestation of, and synonymous with erythroblastosis, especially if the distribution of the Rh factor in the family is of the type characteristic for erythroblastosis, father and child positive, mother negative. This is an extreme view likely to lead to inclusion of cases which have nothing to do with erythroblastosis with resulting confusion. No student of the subject will deny that there are instances of hemolytic anemia of the newborn which are not erythroblastosis foetalis. Septic infections, neonatal and prenatal bronchopneumonia

may be associated with severe hemolytic anemia. It is sometimes extremely difficult and even impossible to diagnose the underlying infection clinically. Only an autopsy may reveal it.

The diagnosis of erythroblastosis is not always easy, especially in mild abortive cases, and an autopsy may be essential for a definite diagnosis. There are instances in which even autopsy findings may not be unequivocal, especially in premature infants and in stillbirths. In such cases a study of the Rh factors in the parents and child and of anti-Rh agglutinins in the mother may be of considerable help in arriving at a correct interpretation. It has already been stated that this cannot be relied on too implicitly and I have had one example of an Rh positive husband of an Rh-negative mother of a perfectly healthy Rh-positive infant, with well developed anti-Rh agglutinins in the mother. Levine¹⁵ reported similar findings in two women.

Illustrative Cases

Two cases will be quoted to illustrate the role of tests for the Rh factor in obscure blood disease in infants.

CASE I—A five-month-old white girl, patient of Dr. E. Padnos, was admitted on July 12, 1943, suffering from a severe anemia, with a history of jaundice at birth lasting for over a month. The child did not thrive well and passed bloody stools on several occasions. She was very pale. The spleen and liver were palpably enlarged.

The accompanying tabulation summarizes some of the blood findings. The differential blood smears showed marked macrocytosis, moderate anisocytosis, poikilocytosis and hyperchromia, and slight polychromatophilia. The reticulocytes were 3.6 per cent, platelets 108,000, coagulation time nine minutes, bleeding time over ten minutes, icterus index 11 and 13. The fragility test showed normal values. Serologic tests for syphilis were negative.

In view of the history of jaundice at birth and of the severe anemia, hemolytic disease of the newborn was considered. The father and the child were B Rh-positive, the mother O Rh-negative. There were no demonstrable anti-Rh agglutinins in her serum. The father was used as donor in both transfusions. The use of an Rh-negative donor was not considered necessary in view of the age of the child. Any antibodies that the child may have had at birth would have been eliminated by this time.

The child left the hospital eighteen days after admission very much improved, and has remained well since.

* Per 100 white blood cells

Was this a case of erythroblastosis foetalis? The history of prolonged jaundice at birth, the clinical picture and hematologic findings would fit into that diagnosis. Purpura is not infrequently observed as a complication. The prompt response to transfusions is also more commonly seen in this disease than in other blood disorders. Finally, the Rh formula in the family is in favor of the diagnosis of late erythroblastosis foetalis with purpura.

Another diagnostic problem presented itself in Case II.

CASE II—A five-month-old girl, patient of Dr. B. M. Gasul, was admitted with a history of extreme restlessness with rigidity of the body and retraction of the head for the past two months. The weight at birth was 8 pounds and was the same on admission. The child was born at term, the delivery was spontaneous. The mother stated that the child became jaundiced at the age of four days and that jaundice persisted for two months.

The red blood count was 4,830,000 and 5,380,000; the hemoglobin was 15.4 gm (92.4 per cent) and 14.9 gm (89.4 per cent). The other findings including the differential blood count were not remarkable. Serologic tests for syphilis were negative.

In the course of blood grouping and crossmatching tests it was found that the serum of the mother clumped cells of groups A, B, O and AB, though she was of group AB. Serum of group AB should not clump cells of any group. It was established that she was Rh-negative and had strong anti-Rh agglutinins, that her husband was A Rh-positive, and that the child was AB Rh positive. This was the third child in the family, the first, a girl five years old, was normal, the second a three-year-old boy was jaundiced at birth but had been well since.

In the differential diagnosis between birth injury and a residual involvement of the central nervous system with Kernicterus due to icterus gravis, the serologic findings of an Rh formula typical for erythroblastosis foetalis and of anti-Rh agglutinins in the mother favored the last mentioned diagnosis.

Kernicterus with spastic manifestations and evidence of mental deficiency has long been considered a late complication of icterus gravis. This case shows the value of Rh tests in such cases. In view of the opinion that some forms of juvenile cirrhosis may be another residual condition after erythroblastosis, as a result of severe hepatic damage, studies of the Rh factor in such families may be of interest.

TESTING FOR THE RH FACTOR

Testing for the Rh factor may be done either with animal (guinea pig) or with human immune serum. The serum of guinea pigs, immunized with rhesus blood, may show significantly higher titers for Rh-positive blood.

Human serum with anti-Rh agglutinins may be obtained, rarely, from Rh-negative patients who had received repeated transfusions of Rh-positive blood, and more frequently, though still rarely, from Rh-negative mothers of babies with erythroblastosis.

For technical details regarding preparation of animal serums and their uses, detection of anti-Rh agglutinins in human serums and their uses, elimination of interfering isoagglutinins, crossmatching tests for Rh incompatibility, which can be done without available anti-Rh serums, the interested reader is referred to the bibliography ^{8, 9, 16, 17, 22, 23}

PRACTICAL APPLICATIONS

Repeated Transfusions

Patients who are receiving repeated transfusions may benefit by having their blood tested for the Rh factor. If it is found negative and if Rh-negative blood is available it is advisable to use it for two reasons: reactions will be avoided if the patients have become sensitized previously, otherwise sensitization will be prevented. Experience has shown that severe hemolytic reactions in patients receiving repeated transfusions have, as a rule, been preceded by mild or moderate reactions which have been disregarded. The lesson from this is to test for the Rh factor the patient who is receiving repeated transfusions and in whom a reaction, especially with hemolytic features, has been observed.

It should be noted that the sensitive crossmatching technique for Rh incompatibility may give a patient in need of transfusion a measure of protection even if Rh tests are not done.

Transfusions in Pregnancy

Pregnant women, or those recently pregnant, should receive the benefit of the new knowledge. They are especially in danger if there is a so-called bad obstetrical history of previous births of babies with edema, jaundice, and of stillbirths. Rh-

negative donors are to be used, of the same group as the patients, or of group O. The latter when Rh-negative are better than Rh-positive ones, even of the same group as recipients. The husband should not be used, unless expert serologic tests have eliminated any evidences or even possibility of isoimmunization during pregnancy.

Transfusion Therapy in Erythroblastosis Foetalis

Transfusion is the therapy of choice for newborn children with any manifestations of erythroblastosis. It is important that blood be given as early as possible and that indications for further transfusions be controlled by the condition of the child. It is essential that Rh-negative blood be given, although the infants are Rh-positive. It is assumed that they may have some of the anti-Rh antibodies in their circulation or attached to the reticulo-endothelial system, ready to react with injected Rh-positive blood. If known Rh-negative blood is not available the next best course is to use the mother's blood cells, after the plasma is removed and the red cells washed twice with sterile saline and resuspended in sufficient saline to make up for lost volume. This is always a safe procedure because an infant never has isoagglutinins in his serum directed against the cells of his mother.

It has been recommended that mothers be not permitted to nurse infants with erythroblastosis, because anti-Rh agglutinins have been found in breast milk.⁴

The results of prompt transfusion therapy in erythroblastosis have been extremely gratifying. Javert¹⁹ reported a drop in mortality from 73 per cent to 14 per cent since 1941 in his series. This success is especially significant in view of the fact that erythroblastosis has been listed as responsible for 3.2 per cent of fetal and infant mortality.

THE RH FACTOR IN OBSTETRICS

EDITH L. POTTER, M D, Ph D *

THE discovery of the Rh factor and its correlation with clinical material has led to the establishment of an etiologic basis for certain intragroup transfusion reactions and for erythroblastosis foetalis, two conditions the cause of which had previously been unknown. Both are extremely important in the practice of obstetrics because of the large number of transfusions given in the immediate postpartum period, and because of the poor prognosis for future childbearing in a woman who has once given birth to an infant suffering from erythroblastosis. A relationship between transfusion reactions in the mother and erythroblastosis in the offspring was first recognized by Levine, Katzin and Burnham¹. In the short time that has elapsed since their observations were made, much clinical data has been accumulated which substantiates their findings, and gives a broader understanding of the processes involved.

GENERAL CHARACTER OF THE RH FACTOR

The Rh factor is an antigenic substance present in the red blood cells of 85 per cent of the white population of the United States² and England³. It was discovered by Landsteiner and Wiener⁴ in 1940, who found that rabbits inoculated with red blood cells from the monkey, *Macacus rhesus*, produced antibodies capable not only of agglutinating the blood cells of the *Macacus rhesus* but also the cells of a large number of human beings.

It was thus evident that rhesus blood and most human blood contained a common antigenic factor, which, because of the association of the monkey with its discovery, was designated Rh. Those individuals whose blood contained the antigen and would react with the rabbit serum were considered Rh-positive.

* Assistant Professor of Pathology, Department of Obstetrics and Gynecology, University of Chicago School of Medicine, Pathologist, Chicago Lying-in Hospital

(Rh+) while those whose blood failed to react were considered Rh-negative (Rh—)

The presence or absence of the Rh factor is in no way related to sex or to the other previously known blood groups A, B, O and M, N. It is like M and N insofar as isoagglutinins against it are never normally present, and differs in this respect from A and B, for which isoagglutinins are always present except in AB individuals who possess both antigens (anti-B agglutinins in A individuals, anti-A in B individuals, anti-A and anti-B in O individuals). However, unlike M and N, isoagglutinins may be produced by the introduction of Rh-positive cells into the circulation of an Rh-negative individual.

The Rh factor appears to be limited to red blood cells and is not present in other body tissues and fluids. A and B, on the other hand, are disseminated widely throughout the body in the majority of all individuals. In some (about 20 per cent who are termed "nonsecretors") A and B are also found only in blood cells. The possibility of the transmission of the Rh antibody to breast milk has been considered, but to date has been demonstrated in only one case^{5*}.

Like the other blood groups, the Rh factor is inherited as a mendelian dominant. It involves a pair of allelomorphic genes Rh and rh, Rh (Rh-positive) being dominant over rh (Rh-negative). Both the genotypes Rh Rh and Rh rh will be Rh-positive, while only the genotype rh rh will be Rh-negative. Assuming random mating, 36.9 per cent of the population is Rh Rh, 47.7 per cent Rh rh, and 15.4 per cent rh rh. It would be possible for two heterozygous Rh-positive parents to have an Rh-negative child, but impossible for two individuals who are Rh-negative to have an Rh-positive child. This fact is of medico-legal significance in the establishment of parentage, and of genetic interest in relation to the diagnosis of single and double ovum twinning.

The Rh factor, like A and B, is not uniform in distribution in different races. Relatively few studies have so far been made but these indicate the incidence of Rh-positive individuals is much higher among American Indians⁷ and Chinese⁸ living in

* Witebsky and Heide (*Proc. Soc. Exp. Biol.*, 52 '80) have subsequently reported two additional cases. A high titer of agglutinins has also been demonstrated by I. Davidsohn in the breast milk of a patient delivered of a baby with erythroblastosis at the Chicago Lying-in Hospital.

this country and somewhat higher among the American Negroes⁹ than among the remainder of the population. Only one Rh-negative individual was found among 169 reputedly full-blooded Indians, and in Indians of mixed parentage the incidence of Rh-negative individuals was halfway between that found for white and for full-blooded Indians. It has been postulated for Rh as well as for A and B that early mutation from the O and the Rh-negative state plus geographical segregation is probably responsible for the present proportions of individuals with A, B, O blood groups as well as for those who are Rh-positive and Rh-negative^{6, 10}.

RELATION TO TRANSFUSION REACTIONS

Prior to the discovery of the Rh factor in 1940, occasional cases had been reported in which severe or fatal transfusion reactions had occurred despite the use of blood of the same group, and many more had been observed which had not been reported. It was presumed that these were due to atypical agglutinins or hemolysins and in a few cases such antibodies were demonstrated. Anti-M agglutinins were found in five cases,¹¹ and the majority of the other reactions appear to have been probably due to anti-Rh agglutinins.

Levine and Stetson¹² in 1939 demonstrated an agglutinin in the blood of a patient recently delivered of an extremely macerated fetus which reacted with approximately 85 per cent of the bloods with which it was tested and they postulated that the retention of the dead products of conception had immunized the mother. The experimental antibodies produced by Landsteiner and Wiener⁴ and reported in 1940 were found to be almost identical in their reaction to those from the patient of Levine and Peters. Although the terminology is based on the experimental animal work, the first demonstration of the Rh antibodies was actually clinical.

The explanation of these intragroup reactions due to Rh immunization is based on the fact that, although antibodies against the Rh factor are not normally present, they may be produced in susceptible Rh-negative individuals by the introduction of Rh-positive cells into their blood stream. It is believed that this introduction of cells may be accomplished either through the administration of Rh-positive cells by transfusion, or by the transfer of fetal Rh-positive cells to the maternal

circulation during pregnancy. It has been presumed that a pathologic state must exist and that a break in the placental vessels necessary for the entrance of cells into the maternal blood stream. Karher¹³ suggests, however, that a physiologic intra-uterine destruction of red blood cells may cause a breakdown of the hemoglobin into molecules small enough to pass through the intact placenta, but large enough to retain their antigenic capacity.

In either case, the mother, in order to become immunized during pregnancy, must be Rh-negative, the father must be Rh-positive, the fetus must inherit the Rh-positive character from the father. The fetal cells or their antigenic components must enter the maternal circulation. The maternal organism must be capable of reacting and producing antibodies.

After anti-Rh agglutinins have once been produced and the patient has become sensitized to the Rh factor, the subsequent introduction of Rh-positive blood, even though it is of the same major blood group, will be followed by agglutination of the donor's Rh-positive cells by the recipient's anti-Rh agglutinins. The reaction between Rh-positive cells and anti-Rh agglutinins can be as disastrous as it would be between group B cells and anti-B agglutinins if blood of a group B donor were given a group A patient.

Probably the majority of Rh-negative individuals have, in the past, been given Rh-positive blood when they have been transfused, and it seems somewhat strange that evidence of the production of antibodies has not been more frequent. The amount of blood, the number of injections and the time interval between injections necessary to produce antibodies in the human are not known but it appears that even with multiple transfusions conditions are not often optimum for antibody formation.

It is also true that individuals vary in their capacity to produce antibodies, and that the antibody-stimulating capacity of various antigens differ. It is probable that, in the majority of Rh-patients who receive more than one transfusion, the transfusions are either too close together or too far apart to be effective in antibody production.

During pregnancy, however, a chance for the continued introduction of Rh-positive cells into the circulation exists for a period of several months. The Rh antigenic property appears very early in fetal life and was present in five fetuses examined

by Bornstein and Israel,¹⁴ the youngest being 13 cm. in length. Transfusion reactions due to anti-Rh agglutinins consequently appear more commonly in women who have been pregnant, and especially in those whose infants have given evidence of being affected by the antibodies, than in nulliparous women, or men.

RELATION TO ERYTHROBLASTOSIS

Many years before the discovery of the Rh factor it had been postulated that maternal immunization against the products of conception, particularly when the fetus was of a blood group incompatible with that of the mother, might be responsible for maternal toxemia or for infant or fetal death. It was felt that this was especially apt to be true in those cases where the latter was associated with jaundice in the offspring.¹⁵ Many papers had appeared on erythroblastosis and numerous suggestions had been put forth as to its etiology. Macklin¹⁶ had attempted to show a definite hereditary tendency but was unsuccessful. Two facts which were known from clinical experience had to be taken into account in arriving at any conclusion regarding etiology. These were (1) the rare occurrence of the disease in first pregnancies, and (2) the almost constant repetition in all subsequent pregnancies after the disease had once occurred. Darrow,¹⁷ after reviewing the literature dealing with erythroblastosis and considering all the possibilities, concluded that the only explanation sufficient to explain its etiology in view of known facts was that the disease was a response on the part of the fetus to antibodies which it had been responsible for producing in the mother.

Outline of Theory

The early clinical investigations of the Rh factor revealed that the majority of the patients in whom antibodies similar to those of Landsteiner and Wiener could be found had not only been recently pregnant, but had given birth to infants with erythroblastosis. As a result of this, the blood of all available women who had given birth to such infants was examined and a very high percentage were discovered to be Rh-negative, in contrast to the low percentage in the general population. It was therefore concluded that the manifestations of erythroblastosis were probably due to the action of maternal antibodies on the fetus.¹ The theory of etiology is based on the fact that when an Rh-negative

woman married to an Rh-positive man conceives an Rh-positive child, the Rh-positive blood cells from the fetus may pass through the placenta and produce anti-Rh agglutinins in the mother. These, in turn, pass back through the placenta to the fetus and cause the hemolysis of fetal cells which is characteristic of erythroblastosis.

Sufficient evidence has accumulated to put this theory on a firm basis. It appears that at least 90 per cent of all women giving birth to infants with erythroblastosis are Rh-negative, that practically all fathers, and all infants themselves, are Rh-positive. Anti-Rh agglutinins, however, cannot be demonstrated in a fairly high percentage of women giving birth to infants in whom the diagnosis of erythroblastosis has been definitely established. They are more apt to be demonstrable one to two weeks following delivery than at any other time. Levine and his co-workers² found them within two weeks after delivery in about 50 per cent of their patients, after two months in only 10 per cent. They have been observed, on the other hand, as late as six years following the last pregnancy.¹⁸

It is believed that, in those patients whose blood does not contain demonstrable agglutinins, the agglutinins are fixed in the reticulo-endothelial system and although capable of exerting a harmful influence on the fetus they are not free in large enough numbers to be detected. In approximately 12 per cent of all marriages the wife will be Rh-negative, the husband Rh-positive. About 9 per cent of all pregnant women are Rh-negative and give birth to Rh-positive offspring. The potential set-up for erythroblastosis is thus present in almost one out of ten pregnancies, but is actually manifest in only one in four hundred or more. The principal reason why it does not occur with greater frequency is probably because except in rare instances the placenta remains intact and does not permit the escape of fetal cells. Differences in antigenic capacity of the fetal cells and the antibody-forming activity of maternal tissues may also influence the incidence of the disease.

In the Light of This Theory, Why Do Some Rh positive Women Give Birth to Infants with Erythroblastosis?

The 10 per cent of women with infants having erythroblastosis who are Rh-positive fail to meet the requirements for this theory. There are four possible explanations that an error has been made

in performing the agglutination test, that the diagnosis of erythroblastosis is in error, that antigens other than the Rh can cause isoimmunization of the mother, that erythroblastosis cannot be considered an entity, but is a clinical syndrome capable of being produced by various etiologic agents

At times all of these conditions seem to act, the first two, I believe, being more often responsible than the others. In a series of Rh determinations reported by Potter, Davidsohn and Crunden,¹⁸ six of sixty women giving birth to infants on whom a diagnosis of erythroblastosis had been made, were Rh-positive, the remainder Rh-negative. Five of these six infants were badly macerated and the diagnosis was based on moderate enlargement of spleen and liver, edema greater than that usually due to maceration and evidence of an increase in nucleated cells in the clots within the blood vessels of various organs. The tissues were too badly degenerated to permit detailed histologic examination. In each case this was the only fetus affected and none of these women have been subsequently pregnant. Although these are still being considered cases of erythroblastosis it is entirely possible, especially in view of the Rh-positive status of the mother, that the diagnosis is in error.

In the fifth case, however, there was no doubt that erythroblastosis existed. The mother had had three normal children followed by three pregnancies ending in the delivery of three stillborn fetuses all of which were examined at autopsy and in whom the diagnosis of erythroblastosis was definitely established. This case formed the principal stumbling block to my complete acceptance of the theory of Rh isoimmunization as the cause of erythroblastosis. The patient's blood was examined early in 1941 when work on this problem was first being commenced. A single serum which had had specific antibodies absorbed with purified saliva was used. She subsequently became pregnant and delivered a full term female infant in August, 1943. The cord blood showed 91 nucleated red blood cells per 100 leukocytes an icterus index of 22, and hemoglobin of 14 gm. The child became deeply jaundiced within a short time of birth and the icterus index rapidly rose to 138. It was transfused several times and although alive at five months of age has evidence of a definite kern-icterus.

The blood of the mother was again tested early in this last pregnancy and she was discovered to be Rh-negative. Subsequent testing with eight different immune serums all of which have given uniform results, establishes an error in the original diagnosis, and instead of being Rh-positive she is actually an Rh-negative individual. The blood of this patient has been examined several times during pregnancy and the puerperium. She has always been found Rh-negative but anti-Rh agglutinins have never been demonstrated.

These six cases which were reported as Rh-positive show that some error in laboratory technic was responsible for one such diagnosis, and that possibly the condition was not erythroblastosis in the other five.

In further support of the possibility that an error may be made in the diagnosis of the disease is the fact that all infants with generalized edema, pleural and peritoneal effusions are, by the majority of investigators, included under the term 'fetal hydrops' which in turn is considered synonymous with erythroblastosis. I¹⁰ have recently called attention to the fact, however, that fetal hydrops frequently occurs in the absence of erythroblastosis. Seventeen such fetuses had been observed, and since the publication of a paper on the subject, an eighteenth has been added. Despite excessive accumulations of fluid none of these infants has shown histologic evidence of erythroblastosis. The twelve mothers on whom it was possible to do Rh determinations were all positive, four of these women have subsequently given birth to normal infants.

Gallagher and his associates²⁰ selected twenty women who had given birth to infants with erythroblastosis, the term being used, according to the authors, in the 'broad sense of Diamond, Blackfan and Baty.' Insofar as can be determined from the paper, the presence of jaundice in the infant was the only criterion demanded for the diagnosis. They found nine of these mothers Rh positive and conclude on this basis that Rh determinations of the mothers are of no value in establishing the diagnosis, and that since such a large proportion are Rh-positive, the theory of etiology cannot be sound.

This appears to be another example of inaccurate diagnosis. It is unfortunate that the authors were not more specific as to the criteria on which the diagnoses were based. Jaundice in the newborn however, is by itself no proof that the infant has erythroblastosis. In my experience there have been no cases of erythroblastosis in which all features were typical and the diagnosis could be established beyond doubt in which the mother was Rh-positive.

The third possible explanation—that antigens other than the Rh can cause immunization of the mother—is believed by Levine to account for the 10 per cent incidence of Rh-positive women in his series. He, as well as other investigators, believes that erythroblastosis in these cases is due to the action of other isoimmune bodies in some instances anti-A or anti-B (when the fetus is of a blood group incompatible with that of the mother) or to immune bodies produced by antigens not yet identified. One such possible antigen he has designated Hr.²¹

The fourth possibility—that erythroblastosis is not an entity, but a clinical syndrome capable of being produced by various etiologic

agents—is a contention which had been put forth on numerous occasions prior to the discovery of the Rh factor. It is well known that other conditions, especially sepsis and atresia of the bile ducts, may cause severe illness and jaundice, sepsis and syphilis may both cause marked splenic enlargement, an increase in nucleated red blood cells beyond the limits usually considered normal for the newborn is found not infrequently in babies who are ill from almost any cause, excessive edema usually designated “fetal hydrops” may be entirely unassociated with true erythroblastosis.

If any one of these single characteristics is considered a sufficient basis for the diagnosis of the disease, then erythroblastosis is certainly not a specific entity. However, this seems entirely unjustifiable, for there is a definite syndrome which is characteristic of this disease and none other. There are mild and borderline cases, as there are in almost any disease, in which a positive diagnosis may be impossible. It is better, however, to recognize this fact than to say definitely on insufficient grounds that the disease does, or does not, exist.

Importance of a Correct Diagnosis

Few investigators who have reported Rh determinations have given the basis for the diagnoses of erythroblastosis in the cases they have examined. Since there appears to be a considerable diversity of opinion in the minds of different individuals as to what should be included under this term, it would be extremely interesting if full clinical and pathological reports on all infants who supposedly have erythroblastosis whose mothers are Rh-positive could be published. It would give a much better idea as to the etiologic role which must be ascribed to some other antigen or etiologic agent.

The establishment of a correct diagnosis of erythroblastosis is important in relation to prognosis for future pregnancies. Among fifty women observed by me who have had fetuses or infants die of erythroblastosis, twenty-two have had thirty-seven subsequent pregnancies and all of these infants have had erythroblastosis. Only three have survived. This incidence of repetition in subsequent pregnancies is higher than has been reported by some other investigators, but in any series it is sufficiently high to make the outlook for future childbearing very unpromising.

In questionable cases the Rh status of the father, mother and affected infant may lend support toward the establishment or rejection of the diagnosis of erythroblastosis. It, in itself, how-

ever, is never sufficient ground for making the diagnosis. Unless there is some definite clinical or pathologic evidence that the disease exists the diagnosis should not be made.

TREATMENT OF ERYTHROBLASTOSIS

The treatment of an infant born alive with erythroblastosis is *transfusion with Rh-negative blood*. In the group who do not show an appreciable anemia at birth, transfusion still seems to improve the chance of survival. The infant appears to be benefited by the introduction of cells which are incapable of being affected by the antibodies producing the disease. Anti-Rh agglutinins in the infant's blood have been demonstrated in only one instance, but despite this fact Wiener has shown that Rh-negative cells persist in the circulation longer than do Rh-positive cells.²²

The fragility of cells and bleeding and coagulation time are often normal in erythroblastosis. Despite this, many infants with erythroblastosis show some evidence of hemorrhage, and it is probably wise to administer vitamin K even though it has no therapeutic value in the prevention of hemolysis. Intramuscular or intraperitoneal injections of blood will in no way compensate for failure to transfuse. Other forms of medication have not yet been proved of value in the treatment of this condition. It has been suggested that in women who have previously given birth to infants with erythroblastosis, the artificial termination of pregnancy one to two months prior to the expected date of confinement might be advisable. This suggestion is based on the belief that the longer a fetus is subjected to the harmful effects of maternal antibodies, the more severe the disease will be. These infants, however, are subjected to the influence of these antibodies very early in intra-uterine life and it seems that the handicap of prematurity more than offsets any advantage which may be gained by removal of the infant from the influence of the anti-Rh agglutinins. An exception to this might be in those cases in which agglutinins are demonstrable for the first time late in pregnancy, or in which at this time the uterus shows a marked increase.

PREVENTION OF TRANSFUSION REACTIONS

Although by far the greatest loss of life resulting from maternal isoimmunization is in the fetus, a preventable, and there-

fore more important, loss is to be found in relation to transfusion reactions in the mother.

Any Rh-negative woman who is, or has been pregnant, or who has had previous blood transfusions may have anti-Rh agglutinins in her body. They may, in rare instances, be demonstrable during or after pregnancy even though the infant remains normal. On the other hand, even though their existence is proved by the effect they produce on the infant they may never be demonstrable by any *in vitro* agglutination test. This means that all women who are or have been pregnant should, ideally, have their Rh status determined and, if found to be Rh-negative be given only Rh-negative blood.

If it becomes possible to develop a satisfactory testing serum in laboratory animals, the day may well come when Rh determinations are a routine part of all pretransfusion examinations, and when all Rh-negative individuals will be given only Rh-negative blood. At the present time human serum containing anti-Rh agglutinins forms the greater part of the testing serum which is in use. This is extremely limited in amount and consequently the number of determinations which can be made are relatively few in number. It is impossible to test all pregnant or puerperal patients and in very few clinics is it even possible to test all individuals requiring transfusions. Since it is definitely believed, however, that women giving birth to infants with erythroblastosis possess an antibody even though it cannot be demonstrated, all such should be transfused with Rh-negative blood.

In the absence of serum for routine testing of pregnant or puerperal patients, it is advisable before giving a transfusion to such a patient to cross match the donor's cells and the patient's serum for one hour at 37°C and proceed in the manner recommended by Levine²³ and others^{24, 25}. The anti-Rh agglutinins fall in the category of so-called "warm agglutinins" which react only at body temperature. For this reason they may be missed if the tests are performed at room temperature. Although it is theoretically possible for reactions to occur even though matching at 37°C indicates compatibility, such reactions are extremely rare in actual practice. If reactions do occur they are usually of mild or moderate degree and are almost never fatal. It has been shown that the administration of large doses of alkaline drugs aids in preventing precipitation of hemoglobin in the kidney.

tubules, and in case Rh-positive blood is inadvertently given an individual possessing anti-Rh agglutinins, this form of treatment should be immediately instituted.

SUMMARY

The Rh factor is an antigenic substance found in the red blood cells of 85 per cent of the white population of the United States. Although isoagglutinins against it do not normally exist in those individuals who are Rh-negative they may be produced by the introduction of Rh-positive cells into the circulation either by transfusion or by transmission from the placental vessels during pregnancy.

Intragroup transfusion reactions may occur if Rh-positive blood is used for an individual who has developed anti-Rh agglutinins.

Transmission of anti-Rh agglutinins to the fetus through the placenta may cause a severe hemolytic anemia which is demonstrable at birth or within a few days afterward. This anemia, with its associated findings, is characteristic of erythroblastosis foetalis. The present theory of the etiology of erythroblastosis is as follows: An Rh-negative woman conceives an Rh-positive child by an Rh-positive man. The Rh-positive fetal cells pass through the placenta into the maternal circulation where antibodies against the Rh factor in these cells are produced. These antibodies return through the placenta to the fetus and cause destruction of its blood cells.

All Rh-negative patients should be transfused with Rh-negative blood. It can be assumed, if testing serum is not available, that all patients who have given birth to infants with erythroblastosis are Rh-negative, and consequently, before a transfusion is given to such a patient, careful crossmatching by a special technic should be employed.

CLINICS ON OTHER SUBJECTS

THE TREATMENT OF PNEUMONIA WITH SULFADIAZINE*

Five Hundred and Thirty Three Patients in Two Seasons

ITALO F. VOLINI M.D. F.A.C.P.,† GERTRUDE ENGBRING M.D.,‡

JOHN R. PEFFER M.D.§ and HILDEGARDE SCHORSCH M.D.¶

THE literature on the use of the sulfonamides accumulates very rapidly. The various experimental and clinical reports on sulfanilamide, sulfapyridine and sulfathiazole have indicated the effectiveness of these preparations, so that these drugs have quickly become available for use in the therapeutic armamentarium. The ideal sulfonamide has not yet been achieved as evidenced by the continuous chemical, experimental and clinical research for new sulfonamides.

Sulfadiazine (2-sulfanilamidopyrimidine, $C_{10}H_{10}N_4SO_2$) one of a large number of heterocyclic derivatives of sulfanilamide and the pyrimidine analogue of sulfapyridine, was synthesized by Roblin and his associates in the Research Laboratories of the American Cyanamid Company.

EXPERIMENTAL STUDIES

The studies for absorption, toxicity and chemotherapeutic activity in experimental animals covering a large number of infections and several species of animals were first reported by Feinstone, Williams and associates. These laboratory studies have been surprisingly confirmed in almost all details by the

observations of various clinical investigators Feinstone and his co-workers showed that the drug is readily absorbed, produces higher average blood levels and has less toxicity after similar dosages than sulfapyridine or sulfathiazole. In addition, they found that sulfadiazine maintains its concentration in the blood at a higher level, and for longer periods with a relatively low acetylation percentage than the latter drugs. The newer drug possessed equal or superior effectiveness against various common pathogenic bacteria in the experimental animals. Sulfadiazine was found highly effective in the treatment of experimental Freidlander bacillus B infection in mice. One most important finding to which they directed attention was the fact that the

solubility of acetyl sulfadiazine in urine is much higher than that of the acetyl derivatives of sulfapyridine and sulfathiazole. The results of these studies indicated that sulfadiazine was worthy of an extensive trial in the bacterial infections of man.

Sulfadiazine is one of the most insoluble of all of the medically employed sulfonamide drugs. Nevertheless, it is readily absorbed when administered orally, appearing as rapidly in the blood stream as sulfapyridine and sulfathiazole. The experiment charted in Table 1 confirms the observations of Feinstone and associates, Peterson and associates, Plumer and Ensworth, and Reinhold and his co-workers. Two hours following a single dose of 1 gm of sulfadiazine orally the blood level was 2 87 mg per

100 cc for the free drug, and the same for the total (no acetylation)

The second experiment (Table 2) conducted on a patient with pneumonia, Type XIV, with positive blood culture shows the blood and urine studies for free and acetylated sulfadiazine. Following an initial dosage of 4 gm orally, with 1 gm every four hours until a total dosage of 20 gm was reached in fifty-eight hours of treatment, the temperature reached normal in twenty-six hours.

20 hours	2.75	2.75	56.2	56.88
68 hours	traces	traces	15.9	28.3

Clinical Result: Rapid lysis with return of temperature to normal in 26 hours. Total dose, 20 gm. in 58 hours.

A third experiment using sodium sulfadiazine intravenously in a normal individual was performed by administering a single dose of 4 gm in the form of a 5 per cent solution in normal saline. The actual estimations are indicated in Table 3, which shows the time periods with corresponding blood and urinary determinations.

Despite the fact that over 50 per cent of the drug was recovered in the first twenty-four-hour period, the drug was found in the blood at a level of 2.8 mg per 100 cc at the end

of forty-eight hours. As others have observed, sulfadiazine is readily absorbed, produces a relatively high blood level which is maintained because of delayed excretion. The percentage of

blood conjugation is low compared to sulfapyridine and sulfathiazole. Acetylation in the urine accounts for about one third of the total drug.

CLINICAL STUDIES

Most of our experience has been with the use of sulfadiazine in pneumococcal pneumonia. As a supply of the drug was not continuously available, sulfathiazole and sulfapyridine were necessarily utilized at times during the period under study. While cases treated with the latter drugs may thus be considered as a control series, unfortunately a fair estimate of the efficacy of sulfadiazine as compared with them is not possible for the reason that the latter were used in what we consider to be the milder pneumonia months or seasons, such as late summer and early fall. Comparative reference will be made to sulfathiazole and sulfapyridine treated patients in publications to be subsequently released.

This report deals with 533 patients treated with sulfadiazine at the Cook County Hospital. It comprises two seasons, each of which included the fall, winter and spring months of 1941-1942 and 1942-1943 respectively.

The method of study included routine sputum typing, blood culture, blood counts and urinalysis. Chest films were obtained in approximately 50 per cent of the cases, especially in those in which doubts of any kind arose. These were necessitated particularly in the latter period of the study, in order to aid in conservation of material and technical help. Urinary studies were made daily on a large number of patients to determine the frequency of crystalluria and microscopic and gross hematuria. At present repeated urinalysis is made routinely after the administration of 20 gm. of the drug or upon evidence of renal disturbance.

Dosage and Administration

The initial dose consisted of 4 gm. of sulfadiazine, and was followed by 1 gm. every four hours until normal temperature had been maintained for twenty-four to forty-eight hours, depending upon the severity of the clinical evidence and findings. A careful survey was made after unsatisfactory clinical response, in which case a total dosage of 30 gm. was attained. The sodium salt of sulfadiazine, 5 gm. intravenously, was employed where oral dosage was not feasible. Repeated parenteral injections were regulated by the blood level determinations, which also guided the oral use of the drug. Blood levels were obtained after twenty-four to thirty-six hours of administration. Repetition of blood determinations was guided by the clinical response, complications of the drug, or the disease and the clinical progress. Blood levels of 10 mg. per 100 cc. were sought where the clinical response was not satisfactory.

Sodium bicarbonate or other alkalinizers of the urine were not employed. The senior author has insisted, from clinical observations, that results have been less satisfactory when alkali is administered with sulfapyridine, sulfathiazole and sulfadiazine than when it is not. Some experimental evidence has recently been produced which indicates much greater blood and urine acetylation where alkalis are used concomitantly. Alkalies promote absorption and heighten the total level of sulfonamide in the blood. It is axiomatic, however, that conjugated sulfonamides are chemotherapeutically inactive and probably produce more toxic effects, although they are usually more soluble in an alkaline medium.

The supportive and symptomatic treatment was concentrated

mainly on maintaining adequate body fluids. A urinary output of from 1200 to 1500 cc was the primary factor responsible for freedom from complications of drug toxicity. Oxygen therapy was used in less than 3 per cent of the cases. The infrequency of use of type-specified antipneumococcus serum is interesting. Of the six patients who received serum in addition to the sulfadiazine, five succumbed. Unquestionably some patients in the series had received sulfonamides prior to their entrance to the hospital. The type of drug, method of administration and total dosage we were unable to determine in most instances. In a few cases in which no response to sulfadiazine was obtained, either sulfathiazole or sulfapyridine was given. Only occasionally did

the second drug seem to produce a result after apparent failure of action of the sulfadiazine.

Table 4 summarizes the gross results from sulfadiazine in the treatment of 533 patients with pneumonia.

Table 5 illustrates the evidence as broken down from the total of 150 patients with typed pneumococcus pneumonia treated with sulfadiazine during the season of 1941-1942. The rather unusually favorable results cannot be attributed to a mild season with low virulence pneumococci, because over 70 per cent of cases were found to be the more serious types of infection, with bacteremia in 20 per cent.

Data given in Table 6 covers several important features which call for elaboration. Five patients, all of whom died, had meningitis when treatment was started, and received large amounts of

type-specific serum in addition to adequate sulfadiazine therapy. In eighteen of the forty-one fatal cases, treatment with sulfadiazine was started on the fourth day of the disease. Seventy-six per cent of the patients were over forty years of age, and 75 per cent of the deaths occurred in individuals over forty years of age.

The average dose of sulfadiazine was 35 gm, particularly confined to 244 patients (63.5 per cent) who showed normal temperatures within a maximum of seventy-two hours of beginning treatment with sulfadiazine. Seventy-five patients (20.6 per cent) responded to therapy in twenty-four hours, 122 (31.8 per cent) in the second twenty-four hours, and forty-seven (11.1 per cent) in the full seventy-two hour period. The highest total amount of the drug given was 67 gm over a period of eleven days.

Among the factors affecting the response to sulfadiazine, the most important is the early initiation of therapy. In 113 cases (30 per cent), treatment was instituted within forty-eight hours after onset of the disease. Only five of these were fatal. In 123 cases (32.1 per cent), treatment was delayed between forty-eight to ninety-six hours, and eleven deaths (8.8 per cent) occurred. This delay approximately doubled the mortality. In 117 cases (30.5 per cent) in which treatment was delayed more than ninety-six hours from onset, seventeen deaths (14.5 per cent) occurred.

In the 1942-1943 season, 198 type-specific pneumococcal pneumonias were studied and treated with sulfadiazine (Table 7). The general mortality percentage was twice as high as in the previous season. However, five patients were admitted with meningitis before treatment with sulfadiazine was started and four more succumbed within twelve hours of admission. This correction alone would bring the percentage mortality to 5 per cent in 1942-1943, thus very closely approximating the 1941-1942 results. Type VII pneumonia was almost as frequent as Type I, and showed particular virulence resulting in high mortality. The incidence of bacteremia was greater in the 1942-1943 series.

Toxic Effects of Sulfadiazine

The toxic effects ascribable to sulfadiazine are tabulated in Table 8. The more severe manifestations occurred after at least

25 gm and in most instances after 36 gm were administered. All of the severe urinary complications cleared up readily upon withdrawal of the drug and the forcing of fluids. While attention must be directed to the high incidence of crystalluria, mention must be made that urine specimens when allowed to stand for long periods before examination frequently show more crystals than freshly voided specimens.

Toxic effects upon the urinary tract can in large part be obviated by maintaining a high urinary output averaging from 1200 to 1500 cc daily. High blood levels have been a guide to

TABLE 8

TOXIC EFFECTS OF SULFADIAZINE IN 533 CASES

	No	Per Cent
Urinary tract	87	25.6
Crystalluria only	42	11
Hematuria	57	14.8
Microscopic	54	13.9
Gross	3	0.89
Oliguria	1

Leukopenia 4000 and below	10	2.6
Drug fever	7	2
Rash	1	0.3
Nausea	2	0.6
Psychosis from drug	1	0.3

the danger of urinary complications. Adequate blood levels have been found to average 8 to 10 mg per 100 cc. Very high levels are occasionally obtained on the four-hour dosage method. In the series of cases studied, urinary complications have been infrequent due to relatively small total dosages. Over a longer time period, the ascertainment of the blood levels and the maintenance of high urinary output

Complications of Pneumonia under Sulfadiazine Therapy

Two pleural effusions were observed, with no organisms found. Four patients developed empyema while under therapy, an incidence of 1.1 per cent. One fatal case of acute endocarditis was found on postmortem examination. Five patients had meningitis, all dying despite combined serotherapy and chemotherapy. Delayed resolution was encountered in five instances. Otitis media appeared only once.

CONCLUSIONS

Sulfadiazine is particularly effective in the therapy of pneumonia. It is more active against a greater variety of organisms producing this disease. It is without effect in the primary atypical pneumonia in the majority of cases, although occasional sudden defervescence of fever occurs upon sulfadiazine therapy. Despite the relative insolubility of sulfadiazine in water, oral administration results in rapid absorption with a much higher blood level than is usually obtained from related sulfonamides. This high blood level is more easily sustained on average therapeutic dosage.

The percentage of conjugation in the blood is lower than with the related compounds, usually averaging about 10 per cent.

Excretion through the kidneys is relatively slow, which probably accounts for the sustained high blood level of the drug. The acetyl derivative in the urine constitutes about 30 per cent of the total drug. The most frequently encountered and reported toxic effects are upon the urinary tract.

The complications of pneumonia have been observed much less frequently in the sulfadiazine-treated patient. Sodium sulfadiazine has been used by intravenous injection without dangerous complications. This parenteral route is frequently necessary and has especial effectiveness in producing a high blood level in a short period of time with pronounced therapeutic benefit.

Based on the experience cited, of the sulfonamides sulfadiazine possesses the greatest therapeutic efficiency and the least toxicity in the treatment of pneumococcal pneumonia.

ERRORS IN THE DIAGNOSIS OF NEOPLASTIC LESIONS OF THE RECTUM, RECTOSIGMOID AND COLON*

JOSEPH B KIRSNER, M.D., Ph.D.†

and

WALTER LINCOLN PALMER, M.D., Ph.D., F.A.C.P.‡

ALTHOUGH numerous writers¹⁻⁸ have emphasized the clinical features and early diagnosis of carcinoma of the colon and rectum, many lesions continue to be overlooked until they are far advanced Rankin⁹ found, in a series of 1725 patients with malignant disease of the rectum, that only 55 per cent were suitable for operation and only 35 per cent of the lesions were resectable Swinton and Warren,¹⁰ in a review of 300 patients with carcinoma of the colon and rectum, reported that the average duration of symptoms at the time of operation was nine months The late diagnosis of tumors of the bowel is attributable in many instances to delay by the patient in seeking competent medical attention¹¹ An even more important cause, according to Rankin, is the failure to make a proper search for the lesion when the patient presents himself with symptoms

The purpose of this paper is to point out the errors in diagnosis committed in seven representative patients in the hope of stimulating, thereby, greater interest in the earlier detection of tumors of the rectum, rectosigmoid and descending colon

Failure to Examine Rectum in Presence of Classical Symptoms of Carcinoma

CASE I—A S, a forty-year-old housewife, had experienced episodes of lower abdominal cramping pain and diarrhea with the passage of many stools containing blood and mucus for a period of ten months A diagnosis had been made of "colitis" for which the patient had been treated with diets and sulfanilamide without relief

* From the Frank Billings Medical Clinic and Department of Medicine, University of Chicago

† Assistant Professor of Medicine, University of Chicago School of Medicine, Attending Physician, Albert Merritt Billings Hospital

‡ Professor of Medicine, University of Chicago School of Medicine, Attending Physician, Albert Merritt Billings Hospital

The physical examination was normal, but the rectal and proctoscopic examinations disclosed a large, firm, fungating mass 7 cm. above the anal ring. The microscopic diagnosis of the lesion was adenocarcinoma of the rectum. A combined abdominoperineal resection was performed, from which the patient made an excellent recovery. Tumor tissue was found in several regional lymph nodes.

Comment—Daniel Fisk Jones¹² has remarked "There is no disease that can be diagnosticated with more accuracy than cancer of the rectum after the patient has once presented himself and, yet, there are few diseases which are diagnosticated so late in their course." The late Frank Billings, according to tradition, is authority for the statement that the function of the consulting physician is to make a rectal examination. It is no exaggeration to say that many rectal cancers are overlooked because of failure to examine the rectum. This neglect is all the more striking in this case because of the persistence of classical symptoms for almost one year.

Carcinoma of Rectum Overlooked in Presence of Other Pathologic Conditions

CASE II—T. R., a seventy-year-old male, had noted difficulty in urination for ten years. Twenty-four years previously he had been ill with "heart disease." There were no symptoms referable to the digestive tract. Physical examination was negative except for obesity. Rectal examination was reported as revealing a grossly enlarged, smooth prostate. The hemoglobin measured 16 gm., the leukocyte count was normal. The urine contained a slight amount of albumin. An electrocardiogram demonstrated left axis deviation and probably a healed posterior infarct. The patient was referred to the Urology Clinic where rectal examination disclosed, in addition to the enlarged prostate, an irregular mass arising from the anterior wall of the rectum 5 cm. above the anal ring. Further rectal and proctoscopic examinations confirmed the presence of the tumor. The microscopic diagnosis was adenocarcinoma.

CASE III—J. T. R., a fifty-four-year-old minister, had experienced itching and burning of the anal region for fifteen months. Rectal examination was described as very painful and apparently never had been thoroughly performed. A diagnosis of fistula in ano had been made for which the patient was treated with local cauterization, the application of gentian violet, and suppositories. The fistula failed to heal. Further inquiry revealed that in the preceding twelve months the patient had experienced numerous episodes of constipa-

tion and diarrhea. For five months prior to admission he had noted an increasing urge to defecate, frequently without result. In addition, a considerable quantity of fresh blood had been passed per rectum six weeks previously. Physical examination revealed an enlarged liver. Rectal examination disclosed a fistula in ano and also a probable mass high in the rectum. Proctoscopy demonstrated a large, nodular, ulcerated, bleeding mass on the anterolateral wall of the rectum 8 cm above the anal ring. The microscopic appearance of the lesion was strongly suggestive of carcinoma. A combined abdominoperineal resection was performed from which the patient made a satisfactory postoperative recovery. Microscopic examination revealed the tumor as an adenocarcinoma which had penetrated the entire width of the bowel wall and had extended to the regional lymph nodes.

Comment—The value of a careful, routine digital examination of the rectum in the diagnosis of rectal cancer cannot be over-emphasized. Certainly there are few procedures which will elicit such valuable information with the expenditure of so little effort, yet there is probably no examination that is more consistently neglected. All cancers of the rectum and at least 75 per cent of all lesions of the rectosigmoid are within reach of the examining finger, the remaining tumors of the rectosigmoid may be visualized through the proctoscope. The attending physician in each case apparently had been misled by the presence of other pathologic conditions (enlarged prostate, fistula in ano). It is of interest to note in this connection that, in 10 per cent of Rankin's series of patients with carcinoma of the rectum, operations for hemorrhoids had been performed elsewhere after the onset of the symptoms of malignant disease.¹³ Case II is noteworthy because of the complete absence of symptoms referable to the carcinoma. Similar cases have been encountered by others.¹⁴ In Case III the original physician had also failed to elicit symptoms which are commonly associated with carcinoma of the rectum.

Importance of Routine Proctoscopic Examination in Diagnosis of Carcinoma of Rectosigmoid

CASE IV—P W, a fifty-seven-year-old fireman, sought medical attention to determine whether or not he had diabetes. He had lost 33 pounds in weight in six months. Physical examination was normal except for irregular pupils which reacted sluggishly to light. Rectal

examination was negative. The blood count was normal. One of several urine specimens contained reducing substances. The Wassermann and Kahn reactions were negative. The stools gave slightly positive reactions for occult blood. Roentgen study of the esophagus, stomach, duodenum, colon and terminal ileum was reported as normal. The patient was given a measured diet adequate in calories, but during the next two months he lost an additional 15 pounds. The continued loss of weight suggested the presence of a neoplasm, and the patient was referred to the gastro-intestinal clinic for further study. Proctoscopy revealed a mushroom-like growth, about 2 cm. in diameter situated on the posterior wall of the bowel 12 cm. above the anal ring. The microscopic diagnosis of biopsies taken from the lesion was adenocarcinoma. The tumor was removed by a local resection of the rectosigmoid. The patient made an excellent postoperative recovery.

CASE V—M. T., a thirty-eight-year old salesman, had experienced burning pain in the rectum for one year prior to admission. The pain had been relieved by the use of suppositories prescribed by a local physician. Fresh blood had been noted in the stools for three months. The bowel movements usually were well formed, but there had recently been an episode of diarrhea lasting several days. Physical examination was normal. Rectal examination revealed only the presence of internal hemorrhoids. The blood count and urine analysis were normal. Examination of a warm stool was negative for parasites. Three stools, obtained during the use of a meat-free diet, gave strongly positive reactions for occult blood. Proctoscopy demonstrated a polypoid, friable, bleeding mass encircling the bowel 12 cm. above the anal ring. The microscopic diagnosis was adenocarcinoma. Roentgen examination failed to demonstrate the lesion seen through the proctoscope.

Comment—Both cases illustrate the importance of a routine proctoscopic examination in the diagnosis of carcinoma of the rectosigmoid. Case IV is of interest in that the only clue to the presence of a neoplasm was continued loss of weight. Case V emphasizes the need for investigation of all rectal symptoms no matter how unimportant they may appear to be. Had this been done one year previously when suppositories were prescribed for rectal pain, it is likely that the carcinoma would have been detected at a stage more favorable for "surgical cure." The failure of the radiologist to demonstrate the carcinoma is not surprising, for the unreliability of the roentgenologic method in

the diagnosis of lesions of the rectum and rectosigmoid is well known

Failure of Roentgen Examination and the First Two Proctoscopies to Demonstrate Carcinoma of Rectosigmoid

CASE VI—L F B, a sixty-one-year-old unemployed male, had noted lower abdominal cramping pain and the presence of blood and mucus in the stools for eight months. He had lost 9 pounds in weight in one week. Physical examination, including digital examination of the rectum, was normal. The blood count and urine analysis were normal. The maximum free hydrochloric acid after the injection of histamine (0.81 mg) was 45 clinical units. Examination of a warm stool was negative for parasites. Stools, obtained during the use of a meat-free diet, contained occult blood. Gastroscopy revealed a normal gastric mucosa. Proctoscopy for a distance of 20 cm was reported as negative. Roentgen examination of the esophagus, stomach, duodenum, colon and terminal ileum was reported as normal. The patient was treated by the use of a bland diet, sedatives, antispasmodics and vitamins. His symptoms persisted, however, and occult blood was consistently demonstrated in the stools. A second proctoscopic examination for a distance of 18 cm was reported negative. The treatment was continued, but inasmuch as the patient's symptoms increased in severity, he was referred to the Gastro-intestinal Clinic, eight months after his initial visit and sixteen months after the onset of illness. Proctoscopy at this time revealed an irregular polypoid mass on the posterolateral wall of the rectosigmoid, 14 cm above the anal ring. Because of the severe pain induced by the procedure and to make more certain of the diagnosis, the examination was repeated with the patient anesthetized by nitrous oxide. The presence of a tumor mass at the rectosigmoid was confirmed, the microscopic diagnosis was papillary adenocarcinoma of the rectosigmoid. Roentgen study of the colon again failed to demonstrate the lesion. A modified Mikulicz operation was performed with removal of the lower sigmoid colon. The patient made an uneventful postoperative recovery. Tumor tissue was found in several regional lymph nodes.

Comment—Two factors contributed to the late diagnosis in this case, namely (1) the patient's delay in seeking medical attention and (2) the failure of the roentgen examination and the first two proctoscopies to demonstrate the carcinoma. It should be noted to the credit of the attending physician, however, that he was sufficiently impressed by the persistent symp-

toms and the continued presence of occult blood in the stools to pursue the search for organic disease. Persistence of symptoms suggestive of carcinoma of the rectum or sigmoid, following negative proctoscopic and roentgenologic studies, not infrequently signifies that the examinations have been inadequate. If, on repeated rectal examinations, the cause of such symptoms is not found, or in the event the procedures have been unsatisfactory, it is advisable to have the patient examined by a physician trained in proctoscopic methods. It is difficult to understand how the proctoscopist, even though relatively inexperienced, could have passed the proctoscope 20 cm on the first examination and 18 cm on the second without encountering the tumor found later 14 cm from the anus. Nevertheless, this was the case, it is not a unique experience for on several occasions growths have been demonstrated by experienced examiners in patients said to have been proctoscoped previously with negative findings.

CASE VII—V C., a twenty-seven-year-old housewife had complained of intermittent lower abdominal cramping pain and flatulence for five years. The stools were soft and occasionally contained fresh blood. There had been no weight loss. The patient had consulted many physicians and had undergone many treatments including the removal of her appendix, without relief of symptoms. Physical examination was normal except for slight pallor of the skin. The Wassermann and Kahn reactions were negative. The maximum free hydrochloric acid injection of histamine (0.51 mg) was 87 clinical units. The red blood cell count was 3,490,000, the hemoglobin measure 95 gm, the leukocyte count was normal. Stools obtained during the use of a meat-free diet gave strongly positive reactions for occult blood by the benzidine test. Roentgen examination of the esophagus, stomach, duodenum, colon and terminal ileum was reported as normal. Proctoscopy disclosed two small polyps on the anterior wall of the rectum approximately 10 cm above the anal ring. Microscopic examinations of the polyps did not reveal any definite evidence of malignant change. Treatment consisted in the use of a bland diet, sedatives and antispasmodics. Two additional proctoscopic examinations within the next ten weeks were normal. The patient seemed to improve slightly, but because of a persistent secondary anemia and the continued presence of occult blood in the stools, she was hospitalized for further study. A second roentgen examination now revealed a polypoid tumor in the midportion of the descending colon. T

well shown in Figure 37 The patient underwent a resection of the sigmoid and descending colon from which she made an excellent postoperative recovery The surgical specimen contained many small up to 5-mm polyps projecting from the mucosa In addition, there were three large polypoid masses each attached to the mucosa

Fig 37 (Case VII) —Polypoid tumor of descending colon demonstrated at second roentgen examination

by long stalks No evidence of carcinomatous change was detected on microscopic examination.

Comment —This case illustrates the importance of continuing the search for organic disease of the bowel in individuals with a persistent secondary anemia and persistent loss of blood in the stools Useless and potentially dangerous treatment had been attempted for five years because of insufficient regard for these

important laboratory findings. This case demonstrates also that a single reportedly normal roentgenologic examination is not sufficient evidence to rule out organic disease if the clinical course and laboratory studies indicate otherwise.

SUMMARY AND CONCLUSIONS

The seven case reports presented re-emphasize the fact that the early diagnosis of carcinoma of the colon and rectum depends upon a thorough investigation of all symptoms regardless of how trivial they may appear. This investigation must include

- 1 A detailed history of the patient's illness
- 2 A complete physical examination
- 3 *Digital examination of the rectum*
- 4 *An adequate proctosigmoidoscopic examination*
- 5 Careful roentgenologic study of the colon
- 6 A routine blood count
- 7 A routine analysis of the stools for occult blood

In the presence of persistent symptoms, secondary anemia, or occult blood in the stools, the search for organic disease must be continued until the cause of the symptoms and the source of the bleeding are discovered.

NATIONWIDE NUMBER

SYMPOSIUM ON CHRONIC DISEASES

INTRODUCTION

IN recent years the medical profession has become more and more aware of the importance of chronic disease, not only with respect to curative measures for the individual patient, but from the broader standpoint of public health as well. We are very apt to think of chronic disease as synonymous with old age, but the studies by Mary C. Jarrett on 'Chronic Illness in New York City' show that nearly half of all the chronically ill persons in this census were under forty years of age. About one third were children under sixteen, chiefly children with orthopedic disorders.

Chronic disease is by no means confined to the disorders of wear and tear. Many of the infections, notably syphilis and tuberculosis, fall in the category of chronic disease, and many of the disturbances of somatic physiology and chemistry also run a chronic course. Thanks to modern medical research, we are learning that many chronic diseases which were formerly considered incurable respond well to rational therapy. The achievements of modern orthopedic surgery put many cripples on their feet again and the new accelerated treatment of syphilis promises to take this infection entirely out of the chronic disease group. The prognosis for pulmonary tuberculosis has improved greatly in recent years, while gold therapy brings renewed hope to many patients with rheumatoid arthritis. Even in diseases of the nervous system the picture has brightened: shock therapy in its various forms offers a very promising field for further investigation.

In her study 'Chronic Illness in New York City' Miss Jarrett points out that chronic disease is always a medical social problem and that chronic patients are in particular need of social service. They are also in need of much better institutional care than they now receive. The writer hopes that after the war one of the results of the present agitation over improved medical care will be better hospital facilities for the chronically ill. The Goldwater Memorial Hospital

only recently built for the chronically ill of New York City, provides an excellent model which might well be followed by other American cities. In the field of chronic arthritis, the most prevalent of all chronic ailments, the present facilities for institutional care are shockingly poor. It is almost impossible to provide first-class institutional care for the arthritic patient unless he has unlimited means, and even then the problem is none too easy.

Studies such as those included in this volume of *Medical Clinics* give the reader a vivid idea of the immensity of the chronic disease problem. They also serve to inspire the practitioner with renewed interest and enthusiasm in the therapy of chronic illness.

RUSSELL L. CECIL

RECENT ADVANCES IN THE TREATMENT OF SYPHILIS

WALSH McDERMOTT, M.D *

IN the past few years a number of innovations have been made in the treatment of syphilis. Evaluation of any method of antisyphilitic therapy requires months or years, because of the long course of the infection. When such innovations are following one another in rapid succession, as they are at present, only tentative appraisals of their worth are attainable.

As the early (i.e., infectious) syphilitic infections present a clinical entity uncomplicated by permanent damage to vital structures, and one in which changes in the status of the infection can most readily be determined by our present methods, it is natural that most of the recent changes in the field of syphilotherapy should be studied in patients in this stage of the disease. Knowledge obtained from the study of the effects of the new methods on early syphilitic infections is being more slowly adapted and applied to both latent and symptomatic forms of the later disease.

Outstanding innovations in the therapy of early syphilis have been the introduction of intensive arsenotherapy by Hyman, Chargin, Leifer and their collaborators,¹ the exhaustive animal experiments of Eagle and Hogan,² the use of fever as an adjunct to arsenotherapy by Simpson, Rose and Kendell,³ and by Thomas,⁴ and the recent pilot experiment reported by Mahoney of the use of penicillin on four patients with primary syphilis.⁵ In addition, the reawakening of interest in the use of bismuth as a part of various systems of intensive therapy is worthy of note.⁶

INTENSIVE ARSENOTHERAPY OF EARLY SYPHILIS

Methods of intensive arsenotherapy in early syphilis fall into three general categories: (1) the five-day drip, (2) combinations of fever and arsenotherapy by syringe for relatively short periods of one or two weeks, and (3) biweekly or triweekly injections of arsenoxide for longer periods (six weeks to six months) combined with short courses of bismuth.

The Five Day Drip.—It is important to emphasize that the real impetus behind all of these intensive systems was supplied by the demonstration by Hyman, Chargin and Leifer¹ that it was possible to cure the majority of a large series of patients with early syphilis in the short period of five days. Following the study of a small series of patients

* Assistant Attending Physician, New York Hospital. Instructor in Medicine, Cornell University Medical College, New York City.

treated by this method in 1935, these workers and their collaborators set up in 1938 a large scale study of the system. Male patients with early syphilis were admitted to the Mt Sinai Hospital, where they received large amounts of trivalent arsenical administered by intravenous drip over a period of five consecutive days. On discharge from the hospital, alternate patients reported to the Bellevue clinic and to the clinic of the New York Hospital for all subsequent follow-up study. We have had the opportunity of following approximately one half of these patients, starting from the time immediately after their therapy had been concluded.

Dosages, Therapeutic Efficacy—A first group of slightly over 100 patients, of whom forty-seven reported to us, were treated with 4.2 gm of neoarsphenamine during the five-day period. As this series was growing, none of the common serious reactions to the arsenic were observed, with the exception of peripheral neuritis, which occurred in 35 per cent of the patients. This complication, as seen in our part of the series, was extremely mild and in itself would not have constituted any serious drawback to the treatment. However, after 109 patients had been treated with favorable therapeutic response and with no untoward happenings, two patients developed toxic encephalopathy, which, in one, proved fatal. Accordingly, the use of neoarsphenamine was discontinued and mapharsen was substituted. Because of this unhappy experience, the Mt Sinai group quite properly became ultra-conservative in the initial dose of mapharsen and the rate at which subsequent dosage was increased. The dose finally attained, and the one recommended by the originators of the treatment, is 1200 mg of mapharsen, or roughly the equivalent of twenty weeks' treatment on the standard regimens.

In the group treated during the preliminary period with a dosage ranging from 0.5 to 1.0 gm of mapharsen, the therapeutic results were only fair (fifteen out of seventy-six were failures in our half of the series). However, no attempt should be made to examine these figures too critically from the standpoint of therapeutic efficacy. In the first place, eleven of the fifteen reported failures were in patients who developed infectious syphilis subsequent to their originally treated infection. In all probability, a few of these, at least, represent reinfections. Of more importance is the fact that all of the members of this group were treated with a total dose which is considered to be inadequate by the originators of the treatment. Yet despite this, the majority achieved good initial therapeutic results. There was no apparent correlation between the dosage and the treatment failures, some patients attained good results with one half of a dose which failed to work in some others. This immediately suggests that, if the effects of intensive treatments are studied from the standpoint of such factors as body weight, possible differences in excretion of the drug and the

like, individualization of the total dosage might be associated with better results

Of fifty-five patients in the group treated with 12 gm of mapharsen, thirty-five were followed for one year after cessation of the treatment. Twenty-nine were classified as apparently well, and six as failures, including four classified as relapse or reinfection. After two years, no new failures had appeared, but a large number of patients had disappeared, so that all we can show as known two-year results from the fifty-five patients originally seen by us are seventeen patients apparently well, and the six failures. It is, of course, extremely probable that the majority of the fifty-five who have disappeared have achieved satisfactory results.

Relapse or Reinfection—Four of the six patients labeled as failures in the group treated with 12 gm of mapharsen, eleven in the group treated with 0.5 to 1 gram of mapharsen, and three in the group treated with neoarsphenamine—a total of eighteen patients—developed infectious syphilis subsequent to the treatment for the first attack of infectious syphilis. These eighteen patients are actually classified as having "relapse or reinfection." It is unfortunate that they cannot be classified more exactly as it obviously makes a great difference in the interpretation of the results as to under which heading they belong. In some instances of recurrent infectious syphilis, one may feel reasonably sure that the patient is having a relapse and not a reinfection or vice versa, but, since these second infections occur at such a short interval after the original infection, as within one or two years it is actually impossible to decide with any degree of accuracy. It is our opinion that the great majority of these cases represent relapses, but this cannot be established one way or the other.

It is of interest to compare the incidence of such second attacks of infectious syphilis in this intensively treated group with that occurring in patients treated by the standard method. In a consecutive series of 102 of our patients with infectious syphilis, who had completed the standard eighteen months' treatment and who have been followed for from one to five years thereafter only two have subsequently developed infectious syphilis, whereas in the series of 163 treated intensively at Mt Sinai Hospital and followed by us there were 18 such cases. The patients in both groups were in the same social and economic level, most of them having been referred from the same agency, so that there is no reason to believe that sexual promiscuity was more prevalent in one than the other. It is entirely possible, as has recently been suggested by Schoch⁷ that when an early syphilitic infection is treated by the longer methods, some resistance to a fresh inoculation develops despite the apparent biologic cure so that these intensively treated syphilitics may actually be more susceptible to reinfection than the members of the group treated by the longer system.

Including all second bouts of infectious syphilis under the heading of failures, Leifer, Chargin and Hyman⁸ reported satisfactory results in 83 per cent of their patients treated with 1200 mg of mapharsen. This approximates the results obtained by the eighteen months' system of the Cooperative Clinic Group.⁹ Although the two series are not strictly comparable, it appears that 1200 mg given in five days by intravenous drip is quite as effective as the longer treatment.

Relative Frequency of Toxic Encephalopathy—Most of the complications of arsenical therapy such as dermatitis, hepatitis and involvement of the bone marrow were encountered infrequently during intensive treatment with mapharsen. The rarity of such reactions is not surprising, since their incidence following the use of mapharsen has not been high in the prolonged systems of treatment and in general has not depended upon the size of the dose. In contrast to this, the incidence of toxic encephalopathy with any system of arsenotherapy seems to bear a direct relationship to dosage. This much dreaded concomitant of arsenic therapy has been characterized clinically by the relatively sudden development during treatment of mental confusion and convulsive phenomena.

In both the neoarsphenamine and the mapharsen series, the incidence of this type of arsenical reaction has been alarmingly high. It is difficult to estimate the exact incidence of encephalopathy among patients treated by standard methods. Certainly its occurrence has been extremely rare. At the New York Hospital it has not been encountered during a seven-year period in which 4600 patients received 56,480 doses of trivalent arsenicals, including both arsphenamines and arsenoxides. In Moore's clinic at Johns Hopkins, it was seen only twice among 45,000 patients treated by conventional methods.¹⁰ In the United States Navy, where facilities for follow-up are excellent, toxic encephalopathy was encountered only once following 1,000,000 injections of neoarsphenamine.¹⁰ These figures must be compared with an incidence of 1.8 per cent of toxic encephalopathy in the neoarsphenamine series and 1.1 per cent in the mapharsen group of the original five-day drip experiment at Mt. Sinai Hospital,⁸ and with the incidence of approximately 1 per cent in a much larger collected series of patients treated by this method. In 1600 patients treated with the five-day drip, there was a fatality rate from toxic encephalopathy of 0.3 per cent, or roughly one in 300 patients treated.¹¹

It should be emphasized that the high incidence of this serious type of reaction is not unique to the intravenous drip therapy, but occurs to the same extent among patients treated by any of the intensive treatments which require only one or two weeks for completion. Deaths due to the treatment of early syphilis are particularly distressing because of the fact that syphilis in the infectious stage is practically always fatal. To be sure, fatal reactions other than toxic enceph-

alopathy will occur in the arsenical treatment of syphilis by whatever system is employed, but, since the development of these other reactions bears no direct relationship to the dose of drug used, and occurs much less frequently when the arsenoxide preparations are used, it is probable that deaths from these sources would be equally few under prolonged or intensive regimens.

Present Status of Method—The crux of the situation in regard to the overall value of the five-day drip and other systems for intensive arsenotherapy of early syphilis lies in the demonstration that by these methods it is possible to achieve therapeutic results at least the equal of those attainable by the prolonged systems in a period of only a few days or weeks, but at a much higher cost in terms of toxic reactions of the nervous system. As it stands now, the five-day drip method has not proved itself to be a satisfactory method for the treatment of syphilis, but the information gained from this clinical experiment of Leifer, Chargin and Hyman has led the way to a drastic shortening of the period of time necessary for the proper treatment of early syphilis.

Combinations of Fever and Arsenotherapy for One or Two Weeks.—Modifications of the original five-day drip technic have been carried out by numerous investigators in efforts both to make the method less complex and to reduce the incidence of encephalopathy. Thomas¹² concluded on the basis of an extensive experience that, when 1200 mg of mapharsen were given by syringe over time periods comparable to the drip regimen, the incidence of encephalopathy was slightly higher. Although this incidence could be appreciably lowered by using less mapharsen (under 1000 mg total dose) during the same time period, the rate of relapse of the syphilis rose correspondingly, exactly as had been noted with comparable low doses by drip technic. By introducing *typhoid vaccine induced fever* into the scheme he sought to achieve the good therapeutic results of the high mapharsen dosage while staying within the safer range of the lower doses. In his first series of 549 such combined treatments, toxic encephalopathy developed seven times (1.28 per cent). The therapeutic results were quite comparable to those obtained by the other prolonged and intensive systems. However, by reducing the mapharsen dosage to below 800 mg over ten days combined with three or four bouts of fever, he has treated over 800 patients since July, 1942, without encountering a single instance of toxic encephalopathy and with no apparent sacrifice of therapeutic efficacy.¹³

For some years Simpson, Kendall and Rose³ have been investigating various combinations of arsenic and *mechanically induced fever*, and in 1942 reported good preliminary results in a small series of patients treated by various combinations of these two agents. We have had no direct experience in the use of these combinations of fever and

chemotherapy Fever therapy, regardless of the method used, is not without its dangers,¹ entirely apart from the dangers of the associated chemotherapy^{14, 15} Whereas fever is the ideal method for the treatment of some forms of neurosyphilis, where the immediate threat of the disease far outweighs any such dangers from treatment, such a situation does not exist in the early syphilitic infections

Biweekly and Triweekly Systems of Intensive Arsenotherapy—Eagle and Hogan² in a series of painstaking and exhaustive experiments, have supplied the fundamental knowledge necessary to solve this challenging problem of how to obtain the beneficial results of the intensive systems without so much attendant risk These workers have thoroughly investigated the time-dose relationship of a number of different experimental systems for the treatment of syphilis in rabbits, ranging in duration from ten seconds to six weeks They found that within these time limits the total amount of mapharsen necessary to cure syphilis in rabbits varied very little If a total dose within certain limits was used, there was surprisingly little difference from a standpoint of therapeutic efficacy whether it was administered over a period of a few hours, a few days, or a few weeks, or whether it was given by continuous drip or multiple syringe injections They point out, from a study of the published data, that the same phenomenon seems to hold true for infectious syphilis in man, i e., that it takes somewhere around 1200 mg of mapharsen to effect apparent cure whether the dose is given by intravenous drip in five days or by multiple injection over a few weeks

Yet, despite the remarkable uniformity of the total dose necessary for cure regardless of how, or (within limits) how long, it was administered, they found that the margin of safety in terms of animal toxicity was very definitely increased in the longer systems and narrowed in the shorter ones Using an essentially constant total curative dose, they were able to predict quite accurately the incidence of serious toxicity which would occur in their animals on a system of any given duration Thus, they have been able to calculate the factor of safety of a treatment of any duration in rabbits, and, applying their calculations to intensive treatments in man, have been able to show that it would have been possible to predict quite accurately the incidence of serious toxicity which has actually been observed with the various intensive systems

Once this fundamental information was obtained, the problem was simply to choose a period of time which would best satisfy the twin demands of speed and safety for the administration of the total dose in the treatment of syphilis in man Eagle and Hogan did not feel that any treatment schedule using mapharsen, which was completed in as short a period as ten or twenty days, provided a reasonable freedom from serious toxic reactions and deaths

Accordingly, in October, 1941, they set up a large scale clinical study of a number of systems of triweekly injections of mapharsen over total periods ranging from six to twelve weeks, some of which were supplemented by bismuth. In addition also on a basis of this work, a treatment system including biweekly injections of mapharsen given over two ten-week periods separated by five weekly injections of bismuth, was adopted by the United States Army Medical Corps.¹⁶ In this latter system, five additional injections of bismuth are given concurrently with each mapharsen course, the over-all duration of treatment being six months.

Study of these various "Eagle systems" is being carried out by a group of some eighty cooperating clinics. During the past fifteen months, fifty-seven patients have been treated at this hospital with the *six-week system*. This consists of triweekly injections of an arsenic oxide derivative (in this series, clorarsen), 40 to 80 mg per injection depending on weight accompanied by weekly injections of 0.2 gm of bismuth subsalicylate, over a total period of six weeks. Not all of the systems under trial included the supplementary bismuth. There is evidence that, when administered with arsenic, the toxic effects of the bismuth are not additive, whereas the therapeutic activity is additive to the arsenical.⁶ Since the preliminary results indicated that the therapeutic results with triweekly systems were superior when bismuth was given concurrently Eagle and Hogan now advise its use in all such systems under study.¹⁷

Our experience with this six-week system has been too limited, in that our series is small and our total period of study short to justify definite conclusions. However, a valid appraisal of the method will be available soon, when the report on over 2500 patients treated by these systems is published by the originators. In our own small experience with it it can be said that the immediate therapeutic results are quite comparable to those obtained by the other effective methods and that thus far we have not encountered any of the serious toxic reactions.

Reports on the therapeutic efficacy and incidence of toxicity of the *six-month system* used by the Army are not available at this time, but it would seem from the experience with the other systems and from predictions calculated from Eagle and Hogan's data that it would be a most reasonably safe and effective system.

Completeness and Permanency of "Cure" by Intensive Methods—Two questions confront the internist who is attempting to evaluate these rapid treatments of early syphilis. First, how long will it be before we can be reasonably sure that these "cures" obtained so quickly can really be considered to be permanent cures. Second, what factors should be taken into consideration in advising a patient with early syphilis as to which of the many systems of therapy should be used?

In answer to the first question The three main threats which hang over an individual infected by syphilis are (1) the possibility of transmission to others, which in a woman includes the offspring, (2) the possibility of developing syphilis of the aorta with resulting formation of aneurysm or involvement of coronary ostia or aortic valves, (3) the possibility of developing neurosyphilis (Other possibilities exist, but are purposely excluded from discussion because of their infrequency)

In regard to the threat of *transmission to others*, when infectious relapse occurs following inadequate treatment for early syphilis, it usually does so relatively soon after treatment has been stopped In Thomas¹⁴ series, the great majority of such relapses appeared within a six-month period, and in Padget's study of the material from Moore's clinic it was found that 84 per cent of such relapses occur within the first two years of the infection, at an average period of nine months following the cessation of therapy¹⁸ Relapse can occur any time during the first few years, but its appearance after four or five years following the discontinuance of therapy is practically unheard of

As far as the development of *cardiovascular syphilis* is concerned, the available evidence at present points to the conclusion that amounts of arsenical therapy which are grossly inadequate for the complete cure of the infection when given on a weekly regimen are actually sufficient to prevent the development of aortic involvement, provided that this weekly arsenical therapy is given continuously during the early stages of the disease^{19, 20} Since, in virtually all of the intensive systems which have been introduced, as much or more arsenic is used as was found to be effective for the prophylaxis of aortic syphilis when given in weekly systems, it would seem that patients treated by the quicker treatments run little or no risk from this threat

When experimental study of the five-day drip was first started, it was feared that there would be a rather high incidence of acute meningal syphilis occurring as a relapse at some time after the treatment Such fears were not borne out by the results, as the incidence of early *neurosyphilis* under the intensive systems has been, in general, quite as low as with the standard technics The possibility of these intensively treated patients developing neurosyphilis ten or twenty years later would seem highly unlikely on the basis of the long experience with the prolonged systems of treatment for early syphilis In general, neurorecurrences appear fairly soon after the cessation of therapy (two or three months),²¹ so that, if a patient shows no clinical or serologic evidence of syphilis and has a completely normal spinal fluid at a period, say, of eighteen to twenty-four months after stopping treatment, the chances of neurosyphilis developing later on are probably negligible

To sum up, if a patient with early syphilis treated by one of these

intensive systems achieves a clinical "cure" immediately and a serologic "cure" within a short period following therapy (six to nine months), has a normal spinal fluid at some time during the second year after the treatment, and maintains this status of clinical and serologic "cure" for a period of five years after therapy, we have every reason to assume that the cure is complete and permanent. As the period of large-scale experimentation with intensive treatments began with the start of the five-day drip study in March 1938, a number of patients treated by these methods have already successfully passed this five years' test.

Which Type of Treatment Intensive or Prolonged, Shall We Recommend to the Patient?—The problem of which type of treatment, intensive or prolonged, to recommend to an individual patient with early syphilis cannot be so easily solved. In the first place, a great deal depends on one's estimation of the *reliability of the patient*. If one is dealing with large numbers of migratory patients who are of a low level of intelligence, uncooperative, and sexually promiscuous, without any doubt the common weal can best be served by the use of a system which can be administered in its entirety during a period of one or two weeks hospitalization, despite the known dangers inherent in such systems. However, by no means all individuals infected with syphilis, whether seen in clinics or in private practice are so unreliable and uncooperative. In our own clinic, which, because of its particular location in the city, draws a group of patients who are mainly laborers or white collar workers, we have found the average level of cooperation to be high. Among this group, 50 per cent of a series of 155 patients with infectious syphilis completed the full eighteen-months' Cooperative Clinical Group system of treatment, and an additional 25 per cent completed the forty-weeks' treatment considered by the Cooperative Clinical Group to be sufficient to prevent infectious relapses.²² As many or even more of the patients seen in private practice are completely cooperative. It would be grossly unfair to subject these groups of patients to the added dangers of the more intensive systems, when equally good therapeutic results can be achieved by some prolongation of the treatment.

Just what will prove to be the ideal total length of such treatments is hard to say, but at the present time it would seem as if some period between six weeks and six months will prove to be the most satisfactory length for the arsenotherapy of early syphilis. It should be pointed out that there are practical limits to the period of time during which it is required that the patient receive more than one injection per week. We have found no particular difficulty in the triweekly schedule with cooperative patients. However it is doubtful whether triweekly schedules over a much longer period than eight or ten weeks or biweekly treatments for more than six months would prove to be feasible even in groups of reasonably cooperative patients.

As there is some evidence that the incidence of toxic encephalopathy is slightly higher in *pregnancy* than in the nonpregnant state,²³ we regard pregnancy, even when accompanied by early syphilis, as a contraindication to the use of an intensive system of arsenotherapy. Our policy is to treat all pregnant women who are syphilitic with the conventional continuous system throughout the entire duration of the pregnancy.

Despite the increased safety of the more prolonged "quick treatments" over the original five-day drip, and the fact that some intensive system is available in almost every locality with a center for the treatment of syphilis, these methods are still in an experimental stage and should not be used by anyone who is not thoroughly familiar with the arsenical therapy of syphilis.

PENICILLIN IN EARLY SYPHILIS

At the meeting of the American Public Health Association in October, 1943, Dr. John F. Mahoney of the U. S. Public Health Service presented the preliminary results of a "pilot experiment" in which four patients with infectious syphilis were treated with penicillin.⁵ All four patients had darkfield positive primary syphilis, three were seropositive at the beginning and the other developed positive serologic tests for syphilis during the treatment. Penicillin was given intramuscularly every four hours for a period of eight days, for a total dosage of 1,200,000 Oxford units. The immediate results, as judged by disappearance of the treponemas, healing of the surface lesions and reversal to negativity of the serologic tests, were as good as those previously observed by any other known method. If the promise held out by this preliminary report is achieved after more extensive study, it is almost impossible to be too enthusiastic about this demonstration. Thus far, the administration of penicillin to man has been remarkably free from toxic reactions so that, if it is proved to be effective against early syphilis, virtually all the hitherto troublesome problems of "quick treatments" for infectious syphilis will have been solved. Unfortunately, because of the small supply of penicillin available, and the great demand upon that supply for use against infections other than syphilis, it is probable that even if further studies confirm its usefulness against syphilis it will be a long time before it is available for general use in this field.

LATENT SYPHILIS

Under this designation are those patients who have definite evidence of infection with syphilis either existing in the history or in the form of repeatedly positive serologic tests for syphilis, but who do not have any other evidence of the disease as shown by physical examination, fluoroscopy and x-ray of the aorta, and examination of

optic atrophy, severe tabetic pains, or in those with or without clinical evidence of neurosyphilis who have markedly abnormal spinal fluids. All others are given a trial on chemotherapy with trivalent arsenical sometimes supplemented with tryparsamide, with fever therapy later on if chemotherapy does not seem to be effective. On an average, the various systems used require two or three years of chemotherapy for completion, whether or not fever is used, and are adapted to a greater or lesser degree to the particular problem presented by the individual patient.

Intensified Methods in Neurosyphilis—Dattner and Thomas²⁵ are conducting a clinical study of a much shortened system for the treatment of neurosyphilis. This consists of induction of fever by malaria in the usual manner followed immediately on the termination of the malaria by daily injections of 0.060 gm. of mapharsen for a total period of only ten days. No further chemotherapy is given, and the spinal fluid is rechecked every six months. They assume that, if the spinal fluid cell count and protein return to and remain normal after this procedure, the syphilitic process is inactive and will probably continue to remain so. The possibilities resulting from this type of experiment and also from experiments with the combined simultaneous administration of arsenoxide and mechanically induced fever are intriguing and deserve further careful study. Unfortunately, however, it will take a period of some years of follow-up before the efficacy of these intensified systems can be proven.

Surgical Treatment of Syphilitic Primary Optic Atrophy—Another method of treatment in neurosyphilis which is under study at present is the surgical procedure of stripping the arachnoid from the optic nerves and chiasm in patients with syphilitic primary optic atrophy. This was introduced in 1937 by Hausman and his associates,²⁶ and some of their reported results have been quite favorable. Our own experience with the method has been quite limited. Only three of our patients, none of whom had associated tabes dorsalis, have been subjected to the procedure, and, in every one of the three, the situation was so complicated with other factors of the disease and the therapy, that no conclusions one way or the other are permissible. Since the evidence that fever therapy can arrest many cases of syphilitic primary optic atrophy is so well established,²⁷ we prefer to use it immediately in almost all cases of this condition. However, we are willing to try the surgical procedure in those patients whose atrophy is progressing despite fever, or in those with syphilitic optic atrophy who show no clinical evidence of associated tabes dorsalis, the reason for separating this latter group being that it might be more likely that the degeneration of the optic nerve would prove to be on a basis of constriction when there is no evidence of a degenerative process in the spinal cord.

CARDIOVASCULAR SYPHILIS

Despite the fact that arsenical therapy has been used for thirty-three years on a large scale in the treatment of syphilis, the question as to its ability to alter favorably the course of aortic syphilis is in doubt. This almost incredible situation has developed partly because of ill-advised use of arsphenamine in the early days of arsenotherapy, and partly because of the general divorce of the internists from the specialists engaged in the treatment of syphilis. During the last decade, largely under the influence of Moore,²⁸ and of the Cooperative Clinical Group,²⁹ the cautious arsenotherapy of aortic syphilis has received much more widespread trial. The impression gained from these studies is that arsenotherapy is definitely worthwhile. However, because of the extreme variability in the natural course of aortic syphilis, it will require considerably more years of follow-up after arsenotherapy to settle the issue definitely. It has been well established, as mentioned above, that arsenical therapy given early in the course of the syphilitic infection will prevent the later development of aortic involvement even though such therapy was too inadequate to prevent neurosyphilis.^{10, 20}

In our clinic, the patients with frank aortic syphilis, that is, with aortic regurgitation or aneurysm, actually receive more prolonged arsenotherapy than any other patients with syphilis. Our system, which is merely a modification of Moore's, consists of alternating courses of twelve weekly injections of an arsenical (neoarsphenamine or arsenoxide) alternated with courses of four weekly injections of bismuth over a total period of four years with no rest periods. Before the initial arsenical course the patient is given ten or twelve weeks of bismuth and potassium iodide to guard against the possibility of reaction around the coronary ostia at the time of the first arsenical. All doses of bismuth are the same, namely 0.2 gm. of an insoluble preparation of bismuth subsalicylate. The initial doses of arsenical are tiny (0.05–0.1 gm. of neoarsphenamine or 0.010 gm. of mapharsen) and during the first twelve week course are gradually increased, never, however, going above 0.3 gm. of neoarsphenamine. During subsequent arsenical courses, if the patient has shown no evidence of untoward effects from the arsenical, the dose is gradually increased to full therapeutic levels (0.4 to 0.8 gm. of neoarsphenamine and 0.4 to 0.06 gm. of mapharsen) and maintained at those levels throughout the remainder of treatment. When the four years of continuous therapy have been completed the patients are given at least one course of twelve arsenical treatments each year thereafter. Patients in congestive heart failure are not treated until compensation has been restored.

Since this system has been in use for only a period of about six years, no conclusions are permissible in regard to its efficacy in arresting the aortic disease. However, it has been used sufficiently long

(in the treatment of over 100 patients with syphilitic aortic insufficiency) to form an opinion of its safety. Using the exact system as outlined above, we have never encountered any reactions such as the Herxheimer or "therapeutic paradox," which could be attributed to the harmful effect of the arsenotherapy on a syphilitic aorta. The only reactions which have been observed are those common to the arsenical treatment of syphilis in general, such as the development of skin sensitivity. It cannot be too strongly emphasized that, entirely apart from any theoretical untoward effect of arsenic on a syphilitic aorta, a patient with aortic syphilis with involvement of the valve or a coronary ostium has heart disease. Any patient with heart disease, regardless of the etiology, might not be able to tolerate one of the so-called minor reactions of arsenical therapy such as vomiting or diarrhea, which would represent no great danger to a patient with a normal heart. The administration of arsenic, just like the administration of any medication to a cardiac, must therefore be handled with caution, but when handled with such caution is a safe procedure.

SUMMARY

The recent advances in the therapy of syphilis have been almost entirely in the field of the more rapid treatment of early syphilis. Fundamental information about arsenotherapy which has been established by the study of these intensive systems in animals and in man is being applied to the treatment of late latent syphilis. The treatment of neurosyphilis is still a prolonged affair despite the greater use of fever therapy. Experimental studies on various combinations of simultaneous fever and chemotherapy may, however, eventually lead to a shorter system of treatment here also. Arsenotherapy of aortic syphilis is a perfectly safe procedure provided that the reasonable caution needed in the treatment of any cardiac is used. Whether it can arrest the progress of the aortic disease is still not established, but its use for this purpose deserves further extensive trial.

ADVANCES IN THE STUDY AND TREATMENT OF RHEUMATOID ARTHRITIS AS REPORTED IN 1942 AND PART OF 1943

CHARLES H SLOCUMB, M.D,* AND HOWARD F POLLEY, M.D †

AMONG the noticeable effects of this war on medical progress has been the stimulation of investigation in such fields as tropical diseases and aviation medicine. From a comparative standpoint, this is reflected as a decrease of the amount of investigation of the rheumatic diseases. Yet the lack of much desirable factual information and the chronicity of some of the clinical entities comprising this field of study make it increasingly important that physicians keep abreast of current studies. For many physicians the demands of either military or wartime civilian practice make this impossible. This résumé of the contributions to a fuller understanding of rheumatoid arthritis published in 1942 and part of 1943 may help to obviate this deficiency.

Not only is rheumatoid arthritis the most frequent cause of the rheumatic symptoms of patients seen by consultants in arthritis in civilian practice but it is also the most difficult to control. While persons in whom this disease has developed are eliminated from military service, rheumatoid arthritis makes its appearance among military personnel and may be expected to develop in increased frequency.

CAUSE

The cause of rheumatoid arthritis is unknown. Hypotheses that have been advanced regarding its cause (infectious, metabolic, endocrine, circulatory, neurogenic) are not generally accepted.²⁷ Serum of patients who had rheumatoid arthritis agglutinated hemolytic streptococci in a higher percentage (58 per cent in a titer of 1/160 or more) than that of controls (13 per cent) and of patients who had osteoarthritis (28 per cent) but this difference could not be regarded as diagnostic or of etiologic significance.¹⁸ Dienes and Smith cultured pleuropneumonia like (L) organisms from prostatic secretion, urethra, cervix or vagina of twenty-three of 129 patients. Two had rheumatoid arthritis, one had polyarticular swelling and four had soreness in fibrous tissue and muscles. No organisms were obtained from the synovial fluid of one patient. This interesting observation needs further study. Angevine, Rothbard and Cecil could find no significant organisms in culturing blood, joint fluid, synovia or subcutaneous nodules.

PATHOLOGY

The reports on pathologic anatomy stress the systemic nature of the disease and again present the changes in joints that account for the progressive damage to the affected joints. Some new observations also are presented regarding pathologic changes in nerves.

Bennett describes the early inflammatory changes in the subsynovial tissue as marked diffuse lymphocytic and plasma-cell infiltration, frequently with formation of lymphoid follicles. Synovial villi were redundant and thickened. Steinberg's biopsied specimens of synovia in a case of acute rheumatoid arthritis showed in addition edema and a polymorphonuclear reaction. In a later stage of the disease a pannus of chronic proliferative inflammatory tissue from the synovia grows over and erodes the cartilage of the joint from the perichondrial margin. When the pannus on one cartilaginous surface comes in contact with the pannus on the other cartilaginous surface of the joint, the inflammatory tissue (pannus) of the two opposing surfaces fuses readily. The healing process of the inflamed pannus is by fibrosis and later often by bony ankylosis. It is because of the predominant tendency for fibrous bands to develop in the joints of patients who have rheumatoid arthritis that it is so important to keep these adhesions stretched out during the course of the disease, if ankylosis or marked limitation of the range of movement of the affected joint is to be avoided. The description of the thinning and damage to the cartilage, of the loss of calcium from the bones and of the mononucleated cellular reaction in the subchondral bone should also be of help in understanding that the affected joints cannot tolerate a normal amount of use without undergoing additional mechanical damage. Therefore it is apparent that the inflamed joints need rest and protection from trauma but also need sufficient purposeful exercise to preserve adequate range of movement.

Rheumatoid nodules occur in 20 per cent of the cases studied by Bennett and by Short and Bauer. When they occur, they present microscopically one of the most characteristic tissue changes of rheumatoid arthritis. Usually these nodules can be well distinguished microscopically from similar nodules present in some cases of rheumatic fever.

Freund, Steiner, Leichtentritt and Price, and Leichtentritt report the finding of small inflammatory nodules on postmortem examination of sciatic and femoral nerves and brachial plexus in five cases of rheumatoid arthritis. These nodules were not apparent to the naked eye without staining. They were located in the perineurium, less often in the epineurium and never were seen in the endoneurium. The nodules consisted of an outer zone of lymphocytes and plasma cells and an inner zone of epithelioid-like cells, and usually there was a central region of necrosis. One gets the impression that these nodules are very

STUDY AND

similar in microscopical nodules of patients

Four studies on nodules in three papers in which cardiac lesions indistinguishable from those reported in sixteen of the three (Bayles³) and The high incidence of rheumatic fever suggests that rheumatoid arthritis not only has cardiac lesions of the heart but few exceptions, from rheumatoid arthritis cardiac lesions (Rosenberg⁴) are very different and the changes in the nodules are different. It is apparent that the usual changes in rheumatoid arthritis differ so markedly from those in rheumatic fever that the pathogenesis of the former, in the absence of evidence to the contrary, seem advisable to consider rheumatoid arthritis as separate from rheumatic fever.

TREATMENT

The permanency of the building up of the patient's joint can be discussed. It is important for the patient to improve general health and fibrous tissue contractures and muscle atrophy. It is an opportunity to build up the patient's strength and control the active disease after the acute phase. Help for the Patient is essential in controlling an acute or subacute stage of the disease. Progression of chronic rheumatoid arthritis is advisable. The affected joint should be kept in case some residual movements should be permitted. Patients showing progressive joint movements in the joint should be kept in the joint and continue with work and continue with work and continue with work, even in this group, to

similar in microscopic structure to the more obvious subcutaneous nodules of patients who have rheumatoid arthritis

Four studies on necropsies totaling 162 cases were reported. In the three papers in which details of the cardiac findings were given cardiac lesions indistinguishable from those of rheumatic fever were reported in sixteen of thirty (Baggenstoss and Rosenberg), six of twenty-three (Bayles⁵) and nineteen of sixty-one (Fingerman and Andrus). The high incidence of cardiac lesions indistinguishable from those of rheumatic fever suggests a relation between rheumatic fever and rheumatoid arthritis not yet understood, yet it must be stressed that the cardiac lesions of the patients who had had rheumatoid arthritis, with but few exceptions, were mild. Clinical study of patients suffering from rheumatoid arthritis shows only a few that have diagnosable cardiac lesions (Rosenberg), the clinical courses of the two diseases are very different and the changes in the joints and the microscopic changes in the nodules are different. Bennett concludes that "It is apparent that the usual anatomic changes observed in rheumatoid arthritis differ so markedly from those of rheumatic fever that one must infer that the pathogenesis of the observed lesions is different. Therefore, in the absence of etiological evidence to the contrary it would seem advisable to continue to look upon rheumatic fever and rheumatoid arthritis as separate and distinct entities."

TREATMENT OF RHEUMATOID ARTHRITIS

The permanency of arrest of active rheumatoid arthritis depends on building up the patient's resistance to control the disease. The treatment can be discussed under three main headings: (1) help for the patient to improve general resistance; (2) proper care of joints, muscles and fibrous tissue to minimize damage in the joints, deformities, contractures and muscular atrophy; (3) temporary control of the active rheumatoid arthritis in the hope that this will give the patient an opportunity to build up his resistance sufficiently so that he can control the active disease after the treatment has been discontinued.

1. Help for the Patient to Improve General Resistance.—Rest^{1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37} is essential in controlling an active phase of rheumatoid arthritis. During an acute or subacute stage of the disease or during a period of progression of chronic rheumatoid arthritis considerable rest in bed is advisable. The affected joints should be placed in the best position³⁸ in case some residual limitation of movement develops. Supervised movements should be performed each day to preserve adequate range of movements in the joints. Patients who have less severe arthritis and patients showing progressive improvement may be moderately active and continue with work provided the affected joints are not traumatized even in this group ten hours of rest at night and a midday rest

period are advisable. The rest must be both physical and mental. Without this rest, the patient cannot put up his best resistance against the disease.

Analgesic agents such as acetylsalicylic acid²⁰ (aspirin) or sodium salicylate given in 10 grain (0.65 gm) doses with an equal amount of alkali are often necessary for adequate rest. The dose may be repeated every four to six hours. Acetophenetidin, aminopyrine and cinchophen may be used for short periods but because of slight risks of toxicity they should be avoided if acetylsalicylic acid or sodium salicylate is adequate for the control of pain. Local applications of heat, counter-irritants or careful movements to "lumber up" the painful region may give sufficient relief. Even though the foregoing measures need to be repeated every three to four hours during the night, one should do this rather than resort to narcotics. Mild sedatives in addition to the analgesics may give more relief than an analgesic alone but it is usually best not to give the sedatives without some analgesic to control the pain.

Mental rest^{12, 24, 30} is also very important. The patient must have confidence that the attending physician is following a schedule of accepted treatment and will be willing to make changes if such should be indicated. The patient does not have the right to expect a change of treatment every few days or even with minor transitory flare-ups and must be willing to work with the physician in evaluating progress. The physician must keep an optimistic but realistic understanding with the patient and should give the patient insight into the problems of his disease.

A well-balanced^{6, 37} diet should be advised for patients who have rheumatoid arthritis. The diet should be high in vitamins and minerals and adequate in proteins and should have calories according to the patient's weight. The patients that are undernourished should be urged to eat irrespective of appetites so that a high caloric intake is assured. The obese patients should reduce slowly to prevent added injury to their weight-bearing joints. Pemberton lists the abnormalities of the gastro-intestinal tract encountered among patients who have arthritis and suggests that supplemental B complex should be given to them. Freyberg¹⁹ well summarizes the value of each of the known vitamins in the treatment of rheumatoid arthritis. There is no specific value in any of them although the requirement for vitamins of a patient who is sick is often greater than that of a normal person. When the patient's diet cannot be well controlled, vitamin supplements may be given. Discussion of vitamin D will be presented later.

Removal of foci of infection cannot be regarded as the removal of the cause of rheumatoid arthritis and should be carried out conservatively, in cases in which such removal will improve the patient's general resistance.³⁷ Boots and McCollom report that improvement usually

2 **Proper Care of the Joints, Muscles and Fibrous Tissue**—Physical therapy cannot be dispensed with in the successful treatment of rheumatoid arthritis.^{37 39} It is the oldest and one of the most valuable forms of treatment for these patients. An appropriate amount of rest has been stressed and is essential but in addition daily slow purposeful movements (not purposeless wiggling of joints) are essential if the intra-articular adhesions and extra-articular fibrous and muscular contractures are to be kept from depriving the patient of a useful (even though not normal) joint. These movements can be carried out most easily after heat has been applied to the affected region. The local application of heat relieves pain, muscle spasm and subjective stiffness and it increases the circulation to the affected area. Light massage over the muscles with the stroke directed to help the return flow of venous blood also aids in circulation and relaxation. Krusen⁵ and Solomon⁴¹ have described very practical means of giving the physical therapy. Owing to the cost of professional physical therapy and its unavailability in many places it is essential to enlist the careful co-operation of the patient in having him and his family carry out the simpler forms of exercises, applications of heat and sometimes even massage to supplement such supervised treatment as is available. Treusch and Krusen have found that four out of five of the patients so instructed felt that their own home efforts were of definite additional help.

During periods of rest the joints should be placed in the best position in case there is limitation of movement in spite of efforts with physical therapy. Joplin and Baer describe and demonstrate with photographs various ways of splinting joints and the use of corsets and braces.

If the affected joints are improving and can tolerate it the patient's work may be his form of occupational therapy. However, supervised occupational therapy may be very helpful in treatment of patients whose joints cannot tolerate usual activities but for whom efforts should be made to keep up muscular strength or increase the range of movement of the joints. Any occupational therapy should be aligned closely with the physical therapy that the patient is receiving. Blodgett presents the "place of occupational therapy in the treatment of arthritis."

3 **Temporary Help in the Control of Rheumatoid Arthritis**.—There are many remedies that have been advocated as being of some help. Most of these have been discarded others have a definite place in the treatment of patients whose rheumatoid arthritis is difficult to control.

Fever therapy produces an apparent improvement of symptoms for hours or a few days. If it is repeated, significant help may be observed in some cases. The fever therapy may be given in any of many ways (cabinet, diathermy, baths, packs or typhoid vaccine). Osborne and his associates prefer to induce a fever of 104° F for four hours although we prefer to raise the body temperature to 100 to 102° F for half an hour and to give the treatment about three or four times a week. Fever therapy should be given only if the patient's general condition warrants its use and should not be repeated until the patient has recovered his strength and weight after the treatment.

No climate²⁵ is a cure for patients who have rheumatoid arthritis although some of them feel better in a warm or preferably a warm dry climate.

VITAMIN D—Large doses of vitamin D have been used in the treatment of rheumatoid arthritis since 1935. The pendulum swing of popularity of vitamin D for the treatment of this disease has now gone far beyond its rightful place. Enthusiastic advertising and publicity have overemphasized part truths and overlooked the rest of the available information. In 1942 and 1943 there are six reports on five series studied (Table 1). In four of the five series, Ertron was used, in the other report three other preparations of vitamin D were used.³³

TABLE 1—VITAMIN D IN THE TREATMENT OF RHEUMATOID ARTHRITIS*

Authors	Cases	Results of Treatment			Dose Units Vitamin D	Toxicity
		Excellent	Good or Fair	Slight or None		
Snyder and others ^{14,16}	24 rheumatoid	6 (25%)	13 (54%)	5 (21%)	100,000 to 500,000 av 200,000 Ertron	None serious, "few" nausea and vomiting, elevated non-protein nitrogens of 46 to 60 disregarded by authors.

The toxicity of vitamin D varies somewhat with various preparations. Early signs of toxicity³⁸ are sweet taste, nausea, vomiting, polyuria, polydipsia and occipital headache. If these early signs of toxicity are ignored, significant renal damage may occur with elevation of the concentration of urea in the blood and of nonprotein nitrogen in the serum and the appearance in the urine of albumin and casts. If toxic symptoms are respected and administration of vitamin D is discontinued with their appearance, no apparent permanent damage is produced. Steck does not report any toxic reactions after administration of ertron. Snyder and his associates^{45, 46} do not report any serious toxic reactions but they observed nausea and vomiting in a "few" cases. They disregarded elevations of the nonprotein nitrogen to 46 to 60 mg per 100 cc of serum in some of their cases. After administration of the same preparation, ertron, Freyberg^{19, 21} noted anorexia or vomiting in eight cases (22 per cent) and polyuria in three (8 per cent). Renal impairment developed in one of the cases in which there was polyuria. Kelchner stopped administration of vitamin D to 25 per cent of the patients treated as listed in Table 1. Usually from 150,000 to 300,000 units of vitamin D daily have been used and in this range of dosage it may be toxic. Any patient getting large doses of vitamin D should be warned of its toxic symptoms so that administration can be discontinued promptly should such toxic symptoms occur.³⁸

There is considerable difference of opinion as to the value of large doses of Vitamin D in the treatment of rheumatoid arthritis. Steck reports excellent results in 14 per cent and fair to good results in 78 per cent of patients treated. The figures of Snyder and his associates^{45, 46} are a little less impressive. Freyberg¹⁹ and Kelchner noted significant improvement in 39 per cent and 22 per cent respectively. One of us³⁸ noted improvement in half (seven of fourteen) of the patients treated. Flare-ups may occur during the treatment. Vitamin D is not a specific remedy for rheumatoid arthritis but in some cases (average about 50 per cent) improvement of symptoms is present during the time vitamin D is given. Objective improvement and a drop of the sedimentation rate of red blood cells occur less frequently. When vitamin D does produce improvement, its beneficial effect is lost within a few weeks of the time its administration is discontinued,^{19, 24} although a few patients⁴⁶ may maintain the improvement without the additional help of vitamin D after its administration is stopped.

Large doses of vitamin D may be worth a trial in the treatment of rheumatoid arthritis provided toxic symptoms are respected and the medication is discontinued or the dose markedly decreased. Its use alone without established measures of proved value is not justified. Vitamin D can be regarded as one of several schedules of treatment supplemental to conservative programs which may be tried if conservative treatment alone is inadequate.

GOLD SALTS—Gold salts have been used in the treatment of arthritis since 1927. Their proper place in the treatment of rheumatoid arthritis has not yet been established but progress in the study of their therapeutic value, toxicity, dosage and mode of action is being made.

Preston, Block and Freyberg have demonstrated that it is the gold (not the sulfur) in the salts that is the active ingredient in the treatment of a form of arthritis produced in mice by pleuropneumonia-like organisms. Cecil, Kammerer and dePrume¹³ cite their own work previously reported and the work of others showing that gold salts have a chemotherapeutic effect (bacteriostatic) on *Streptococcus haemolyticus* and pleuropneumonia-like organisms. Since the cause of rheumatoid arthritis is not known, it cannot be assumed that the therapeutic results in the treatment of rheumatoid arthritis are explained satisfactorily.

Freyberg, Block and Wells²² have demonstrated that most of the gold is retained in the body for weeks or months and is excreted gradually through the kidneys, only a very small amount appearing in the feces. The aqueous solution of gold sodium thiomalate (myochrysine) for intramuscular injection contains 50 per cent of gold. During a course of treatment, 75 to 85 per cent of the gold in myochrysine^{20, 22} is retained and this is excreted gradually over a period of a few months to a year or more. Gold sodium thiosulfate is an aqueous solution for intravenous injection and contains 37 per cent of gold. A larger total dose of the salt is required to get in the same amount of gold and during the first few hours after an injection of the salt the excretion of gold is a little higher than when gold sodium thiomalate is used. Gold thioglucose (solganal-B oleosum) for intramuscular injections contains 50 per cent of gold. It is absorbed more readily than myochrysine and, in order to have an amount of gold retained equal to that retained from the similar injections of myochrysine, about 150 per cent of the dose for myochrysine is required if gold thioglucose is given. Colloidal gold sulfide (aurol sulfide) is a colloidal suspension containing 87 per cent of gold. More than 99 per cent of it given intramuscularly or intravenously is retained in the body but in the colloidal state it has much less therapeutic value than the preparations of soluble gold salts.

The results of treatment have not produced any uniformity of opinion as to the place gold salts should have in the treatment of rheumatoid arthritis. Some authors regard gold salts as the best available treatment for rheumatoid arthritis, others regard their use as justified in only a few cases because of inconclusive beneficial results and high risk of toxicity. Rosenberg has tabulated the results of treatment by twenty-two of the American and British authors. Short collected reports from the literature on 1800 cases in which gold treatment was used. Cures (arrests) were reported in 13 per cent and marked im-

STUDY AND T

provement in 63 per cent. It is apparent that relapses are frequent. In Table 2 the percentage of patients who have relapsed among the patients treated with gold salts is given. Gold, like

cases in controlling the rheumatoid arthritis. From Table 3 however it is apparent that relapses after the treatment are often present. Usually however the patients will improve again if a second course of gold salts is given. Gold like much of the other treatment for rheu

matoid arthritis, is a temporary help to control the rheumatoid arthritis but, because the gold is retained in the body for months, improvement from gold, if it occurs, usually lasts for several months

(a) *Toxicity*—The high toxicity of gold for some persons is the greatest drawback to its use Short's review of the reported cases in the literature shows that one person in 200 (0.5 per cent) of the patients given gold died as a result of the injections of gold Three deaths from toxicity of gold were reported in 1942, one from enteritis¹³ and two from thrombocytopenia with purpura^{34, 44} Significant toxicity was present in 42 per cent,¹³ 38 per cent,³⁴ 74 per cent³⁶ and 81 per cent²³ of the patients However, Cecil¹² and Freyberg and others²² express the belief that serious toxic reactions occur among somewhat less than 10 per cent of the patients treated The most common significant toxic reaction is dermatitis When severe, it may be an exfoliative dermatitis Less commonly encountered are stomatitis, albuminuria or hematuria, enteritis, bronchitis, neuritis, jaundice and particularly damage to the bone marrow as evidenced by agranulocytosis or thrombocytopenia with purpura and hemorrhages One case was reported in which a toxic reaction developed after the patient had received only 25 mg of gold salts, although most reactions that occur are in the latter part of the course or even after the course has been completed In spite of special studies on the treatment of toxic reactions, no effective treatment is yet available^{22, 47} The mild reactions disappear in a few weeks but severe reactions may remain for months

(b) *Dosage*—The dose used by various investigators has varied from 10 mg to 200 mg of the gold salt per injection each week Cecil, Kammerer and dePrume¹³ compare their results obtained after giving various sized doses and different total amounts of the gold salts They observed that the size of the individual dose did not have much effect on the results of treatment The size of the total dose given was much more important than that of the individual dose A total amount of gold salts of 1 gm or more for a course of treatment gave the best results Generally 50 to 100 mg of the gold salt was given weekly after gradually working up to that dosage

Freyberg^{20, 22} found that, when 100 mg of gold sodium thiomalate (myochrysine) (equal to 50 mg gold) was given weekly, the toxicity was significantly greater and the therapeutic value only slightly better than if 50 mg of this gold salt (25 mg gold) was given weekly If 25 mg of gold sodium thiomalate (12.5 mg gold) was given weekly, the toxicity was less but the therapeutic value was also much less Freyberg urges a weekly dose of 50 mg of gold sodium thiomalate or its equivalent, that is, 65 mg of gold sodium thiosulfate or 75 mg of solganal-B oleosum, taking into consideration the gold content and the speed of excretion

(c) *Conclusions on the Use of Gold Salts*—We must conclude that

gold is so toxic to patients that it should not be given until after a trial of from one to three months of conservative treatment and that then it should be given only in case of progression of the arthritis in spite of conservative treatment, and only with a full understanding by the patient of the risk and only to a patient who is willing to co-operate with the physician during the treatment to report any symptoms of pruritus or itching, stomatitis, gastro-intestinal upsets or dermatitis. It is also safest to obtain a specimen of urine, a leukocyte count and a platelet count every week. Gold should not be given by a physician unless he is familiar with the bad as well as the good results. The articles by Freyberg, Block and Wells and by Cecil, Kammerer and dePrume are recommended for a more complete understanding of the use of gold salts in the treatment of rheumatoid arthritis.

OTHER FACTORS CAUSING IMPROVEMENT—In 1942 and 1943 there have been no available reports on the improvement in rheumatoid arthritis during jaundice or pregnancy and only two short reports on vaccine^{10 11}

Histamine and *mecholyt iontophoresis* may be of value in treatment of rheumatoid arthritis to produce temporary improvement for only a very short time. Smyth and Freyberg noted some improvement after treatment in 79 per cent of cases but on re-examination only 11 per cent maintained any of the improvement. Simpler and less expensive procedures than iontophoresis produce equally good results. Much the same local vasodilatation can be produced by mild fever treatments. Bee venom¹⁴ may relieve pain partially but has very little if any effect on systemic manifestations of rheumatoid arthritis. Cobra venom² has very little effect on the symptoms or progress of rheumatoid arthritis.

CHRONIC DISEASES OF THE LARYNX AND TRACHEA

Pitfalls in Diagnosis and Treatment

CHEVALIER JACKSON, M D , F A C S *

AND

CHEVALIER L. JACKSON, M D , F A C S †

CHRONIC diseases of the larynx and trachea are common and among them are many of the most serious that affect human beings. We have gathered together a group of cases that will illustrate some of the most commonly encountered of these diseases, and a few of the many that are beset with *pitfalls for the medical practitioner*.

TUBERCULOSIS OF THE TRACHEAL WALL WITHOUT PULMONARY INVOLVEMENT

CASE I—This girl is eighteen years of age. She has been referred to us for examination of the larynx and trachea by the Medical Out-Patient Department because a suspicion of possible pulmonary tuberculosis remains entirely unsupported. The patient has an occasional dry cough but there has been no detectable fever, no weight loss or abnormal physical signs, the scant sputum obtained after the administration of potassium iodide was negative, the roentgen-ray examination of the chest was entirely negative, the apices being especially clear.

Our laryngeal mirror examination showed no abnormality. On putting down a bronchoscope we found in the lower part of the cervical trachea an epithelial erosion on an infiltrated, growthlike base. We took a specimen of tissue. Microscopic examination of the specimen showed the typical giant-cell structure of tuberculosis, and tubercle bacilli were, after much effort, demonstrated in the tissue.

The diagnosis therefore is definitely *tuberculosis of the tracheal wall without pulmonary involvement*.

Comment—The question naturally arises as to *why sputum examination had been repeatedly negative* in this case when there was an active tuberculous lesion on the tracheal wall.

A partial explanation is that the sputum was scanty, had there been a breaking down, freely discharging lesion the chances of finding bacilli in the sputum might have been somewhat better, but, anyway, it is a curious clinical fact frequently observed at the Bronchoscopic Clinic that in cases of tuberculosis of the wall of the tracheobronchial tree, with no demonstrable lesion of the pulmonary parenchyma, the sputum is practically always negative for tubercle bacilli.

* Honorary Professor of Broncho-Esophagology and Consultant in Research, Broncho-Esophagologic Research Laboratories, Temple University Medical School, Philadelphia

† Professor of Broncho-Esophagology and Director of Broncho-Esophagologic Research Laboratories, Temple University Medical School, Philadelphia

Treatment is of utmost importance. As in all cases of tuberculosis, primary consideration must be given to medical care and management. Though the lesion is quite accessible, and though there is no contra-indication to local treatment, we must not lose sight of the fact that pulmonary tuberculosis will certainly develop unless the strictest kind of antituberculous regimen is instituted, including rest in bed outdoors for say, fifteen hours out of the twenty-four, to increase the patient's resistance. All other details of an antituberculous regimen should be carried out as if the patient had incipient tuberculosis of the pulmonary apices.

One local measure is important. The patient is an incessant talker. She should be restricted to 100 words a day, and this order should be specific and rigidly enforced, to guard against laryngeal tuberculosis. It is utterly useless merely to tell a talkative patient not to talk so much.

CARCINOMA OF THE LARYNX

CASE II—The patient is a man aged thirty two years. The chief complaint in this case is hoarseness of many years duration. A diagnosis of chronic laryngitis was made by a number of reputable physicians, some of whom made a casual examination of the larynx. Roentgen ray studies of the chest were repeatedly negative. The patient is in good general health and except for the hoarseness and an occasional clearing of the throat, as he calls it, he is symptom-free.

On palpation of the neck no nodes are found but on palpation of Adam's apple we detect a broadening of the anterior part of the thyroid cartilage and a fullness and firmness of the usually depressed and yielding cricothyroid membrane.

We have examined the larynx in the usual way with the mirror. At first we saw nothing much amiss. There was certainly no evidence of chronic laryngitis in the part of the larynx easily visible. After repeated mirror examinations we were able to see the anterior wall and there, at the base of the epiglottis and extending down into the anterior commissure and upper part of the trachea, was a diffuse infiltration with an eroded surface suggestive of tuberculosis, syphilis, or malignant disease.

Serologic tests and general medical examination being negative, we took a specimen of the growth and the histologic examination shows a *carcinoma* of the aggressive type known as Grade 4.

Comment—The choice of *treatment* in this case lies between operation and irradiation. If this lesion were a small one near the middle of a vocal cord, the chances of cure on a statistical basis would be 80 per cent. But here we have an extrinsic growth extending from the base of the epiglottis down onto the anterior wall of the trachea and, moreover, the histologic study shows a high degree of malignancy. In such cases the results from operation are nothing like so good as in early small intrinsic cancer. Another point against a favorable result from operation is that growths at the base of the epiglottis usually are accompanied by leakage of the malignant process into the base of the tongue, where complete excision is usually impossible.

On the other hand, the conditions are most favorable for irradiation. The cellular type is of the fourth grade, that is, the type showing least

differentiation, least keratinization, and least pearl formation, with most numerous mitotic figures. This histologic type is the most sensitive to irradiation. It is true that it is the type in which the percentage of recurrences after irradiation is greatest, but operation has nothing better to offer when, as in this case, the growth is extrinsic. For emphasis it is necessary to repeat, in making this statement, that we are not referring to early intrinsic cancer of the larynx, in which there is freedom from recurrence after laryngofissure in over 80 per cent of the cases.

In addition to the histologic type of growth there is another feature of this case that is favorable for irradiation. The growth is all on the anterior wall of the larynx and upper trachea, and is relatively superficial, almost under the skin, one might say. In this anteriorly projecting region far anterior to the spine, the growth can be efficiently irradiated by crossfiring from practically all directions.

As between radium and the roentgen ray the decision, in this kind of case, may well rest upon which agent is the more readily available. Equally good results, in cases of growths in precisely this location, have been obtained by use of each of these sources of radiant energy. With any method of irradiation the utmost care is necessary to avoid the excessive dosage to the thyroid and cricoid cartilages that is certain to result in utter destruction of the larynx by ravages of suppurative perichondritis and necrosis of these radiosensitive structures. At cancer age these cartilages are partly ossified and the ossific areas are prone to stop and absorb a lethal quantity of the radiant energy.

By way of further comment it should be added that, though many cases of chronic laryngotracheal disease require nothing more than general medical care and management, as we will show in other cases, treatment should not be instituted on the basis of a diagnosis of chronic laryngitis made without thorough examination of the larynx, and such examination is never complete unless the anterior commissure is visualized. The pitfall in this case was that the growth was hidden from mirror view under an overhanging epiglottis.

Another point illustrated is the value of *palpation of the larynx and cervical trachea* in diagnosis. Of course, palpation of the neck for nodes, goiter and other tumors is a routine part of any medical examination, but few practitioners avail themselves of the trained touch in the palpation of laryngeal and upper tracheal cartilages. The presence of a new growth was revealed unmistakably by proper palpatory examination, in this case.

CHRONIC TRACHEITIS WITH MOSS-AGATE SPUTUM

CASE III.—This man, who is forty-two years of age, presents somewhat the same problem as the first patient. He is suspected of pulmonary tuberculosis but supportive evidence is lacking. There is no detectable fever, no weight loss, and the

physical signs and roentgen ray examination are entirely negative. The cough is at times annoying but rarely productive. The patient states that at times he is hoarse, but he will then clear the voice by bringing up a small pellet of pearly-looking starchlike sputum mixed with soot or black dust. He says it is never yellow never looks like pus and he has never noticed any streaking with blood. After raising a pellet of this peculiar sputum, his voice usually remains clear for a few hours.

On examination we saw some of the peculiar secretion bridging across both vocal cords and clinging to the posterior commissure. By encouraging the patient to continue clearing his throat we obtained from him a specimen of secretion. On gross examination it was found to be short that is to say that, though adherent, it broke apart like boiled starch and did not pull out in strings. It was somewhat translucent, not opaque like pus. In it were irregular streaks of dark material like the streaks in the gem known as a moss agate. Here we had typical moss agate tracheal sputum as it has been well named. As a matter of routine we had the usual bacteriological examination of sputum. It was not unexpected when the secretion was found to contain no tubercle bacilli, and only a few bacteria insignificant in kind and number.

Examination of the trachea with the bronchoscope revealed a chronically inflamed mucosa, glazed and patchy red in color: the ringed appearance was less sharp than normal branching vessels were conspicuous in some locations invisible in others. Here and there were pellets of secretion apparently similar to the secretion examined.

From the endotracheal appearances, the typical moss-agate tracheal secretion the symptoms and the negative general findings we made the working diagnosis of *chronic tracheitis*.

Comment—Such a diagnosis forms the basis for *treatment* but it should not be taken as final nor as conclusive against sequelar disease. Such a patient requires periodical watching for an indefinite period and meanwhile he can be cured of the chronic tracheitis by appropriate treatment.

What is appropriate treatment for such a case? The ideal treatment for chronic tracheitis is for the patient to change his residence to a warm moist seashore climate. This is not practicable in many cases. Such a change of residence is contraindicated in any patient suspected of susceptibility to tuberculosis, but in a patient with chronic tracheitis a prolonged sojourn in such a climate will be at least temporarily beneficial and often curative.

A dusty occupation should be abandoned or a protective mask should be worn. Nasal breathing should be restored, if impaired as it usually is, even though operation be necessary for restoration. Avitaminosis, if present, should be cured by correction of the diet and the administration of vitamin medication.

The best local application is mono-*p*-chlorphenol, 1 per cent solution in liquid petrolatum. This drug is made by the Eastman Kodak Company. The 1 per cent solution should be inhaled as a spray from an atomizer with a nozzle to direct the spray downward into the larynx. As with all other phenols caution against excess dosage is nec-

essay. Once a day is the limit of frequency and the total amount of spray should be limited. It would be better for the physician, himself, to make the applications, say about thrice weekly, if the patient is not trustworthy.

The *prognosis* in this case is good, but recurrences in such cases are likely if the patient is long exposed to dry, dusty atmospheric conditions.

Incidentally, it is interesting to note that the dark, fuzzy irregular streaking that justifies the name of "moss-agate" tracheal sputum is not soot or black dust from the inspired air. It is hemosiderin derived from phagocytic cells of the blood.

Other Varieties of Chronic Tracheitis—By way of comment it might be well to mention the fact that there are varieties of chronic tracheitis other than this common kind. There is the *atrophic tracheitis* in which crusts are expectorated. They can be seen in the laryngeal mirror clinging to the tracheal wall. This type of tracheitis is best treated in the same way as the preceding form, but the prognosis is not so good because the mucosal glands are atrophied.

Another variety is the *chronic membranous tracheitis* in which shreds of membrane, or sometimes casts, are expectorated. The laryngeal mirror repeatedly used will eventually reveal a mass of membrane coming up to the posterior commissure. This type of tracheitis is usually due to a specific bacterial infection. If this infective agent can be discovered by examination of the secretion or membrane, an autogenous vaccine will be curative. Lacking this, the treatment mentioned in connection with this case will be helpful.

MYASTHENIA LARYNGIS

CASE IV—Here we have the case of a man, aged thirty-two years, a down-and-out professional singer who has lost his voice. His chief complaint is a wrecked career due to hoarseness and what he calls cracking and breakdown of his voice when he attempts to sing in public.

The patient being now beyond hearing distance we may discuss his case freely. It is a common kind of trouble. It may be said that probably a half or three fourths of the professional vocalists go the same way, unless they abandon the vocal career before the breakdown develops.

This patient has been told many times that he had chronic laryngitis. He certainly has no chronic laryngitis now, and it is doubtful if he had it at other times, though of course it cannot now be said what was or was not present in this case before our examination. We have, however, seen many similar cases in which an erroneous diagnosis of chronic laryngitis was made.

When we examined this patient's larynx we found the mucosa normal. When we asked the patient to make a tone of any pitch and to hold it for the longest possible time he would strike the tone with the normal *coup de glotte*, as the singers call it, but instead of being able to hold it, as any singer normally can, the voice would break. That is to say, the tone would suddenly drop in pitch, become rough and weaken, or, at other examinations, gradually fade out and

we had the patient repeat this performance with the laryngeal mirror

in place we saw the normal approximation and vibration of the cords when the tone was struck but instead of this tone being held as a normal singer would hold it, and as no doubt this patient in better days could hold it, the cords relaxed and then parted synchronously with the breaking of the voice.

We have, therefore in this case not a chronic laryngitis, which is a mucosal inflammation, but a muscular disability. This disability is called *myasthenia laryngis*. Parenthetically it should be stated that this has nothing to do with myasthenia gravis, which as you know, is a bulbar trouble. The disease in this patient is local and concerns only the laryngeal musculature.

Comment—The cause of this patient's ailment is vocal abuse. On questioning him about his daily life in his best professional days we discover the same things that ruin the voices of most professional singers. They give their larynges no rest. When not singing or rehearsing they are talking constantly. In all their singing they are striving to increase their range upward. They try to overcome the gradually and progressively increasing failure of their voices by increased vocal exercises and change of method, instead of by prolonged intervals of absolute silence.

What can we do for this man's myasthenia laryngis? Very little. He can never again regain a voice fit for public performance. He can recover a vocal control sufficient for entertaining a few friends in a living room. He had better try some other occupation possibly teaching. Perhaps he is not too old to acquire ability in instrumental music.

The chief reason for presenting this case is to point out how such sad and numerous cases of breakdown in a musical career can be *prevented*. Singers should be taught that there is a limit to what any human larynx can stand without permanent impairment of those exquisite qualities that make a career in vocal music possible. They should be taught that they must not talk all the time they are not singing. In other words on the days when they must sing in public they should limit their vocal exercises and should be absolutely silent as to conversation. These intervals of silence will go a long way toward preventing strain and fatigue and ruin of the laryngeal muscles.

There is one other factor in many instances of wrecked careers of concert and operatic singers and that is *alcohol* as a beverage. Total abstinence is essential for preservation of those highest qualities of voice that make a vocal career possible.

RIGHT LARYNGEAL PARALYSIS DUE TO A SMALL TUMOR LIKE MASS INVOLVING THE RIGHT TRACHEAL WALL, PROBABLY DUE TO TARDIVE GENITAL SYPHILIS

CASE V—Here we have an example of disease of the trachea that is of interest to every practitioner of medicine. This orphan girl is twelve years old. Her voice is not bad, yet she has a paralyzed vocal cord. She has a misleading history. The grandmother states the child has had a chronic cough off and on, all her life; that it was never severe and would often disappear for weeks at a time. A month or

two ago the cough became what the grandmother calls "wheezy" She never noticed that the cough was loose nor that any secretions were brought up

About a week ago the child developed what the grandmother thought was, as she expressed it, "a cold in the throat," for which treatment was sought in the Out-patient Clinic

Mirror examination, done for the first time in this child's life, showed the right vocal cord to be motionless, but the left cord on phonation came across the midline to meet the motionless cord and produced a loud though rough voice

A working diagnosis of paralysis of the right vocal cord was made and the child was referred to the Bronchoscopic Clinic for further study

On examination with the laryngoscope the working diagnosis of paralysis of the right cord and the compensatory adjustment of the left cord were corroborated Passing the laryngoscope through the glottis, a good view of the trachea was obtained About half the lumen was obstructed by a dark red mass projecting from the right side, the upper edge obliterating the fourth ring The mass was pulsating but the pulsations seemed transmitted rather than expansile

To have taken a specimen of tissue with tissue forceps through the laryngoscope would have been quite easy, but we did not do so because the lesion, though it could have been a chondroma, had rather the appearance of a chronic inflammatory condition and the obliteration of the rings suggested perichondritis, which is often due to syphilis The laryngoscope was withdrawn

Palpation of the neck was negative for nodes but palpation of the tracheal cartilages yielded important findings Deep down behind the clavicle on the right side, the rings merged into a small tumor-like thickening that was probably integral with the trachea, on swallowing, the trachea and the thickening moved up and down together Pulsations could be felt but the sensation they gave to the examining finger was that of transmission rather than of expansion

General and roentgen-ray examinations of the child revealed no stigmata or other significant findings Both parents had died by accident, so the question of syphilitic parentage could not be determined The serologic test was negative but had not yet been repeated

Three successive serologic tests were then made The first one was doubtful, the second and third were both positive (1 plus) These if supported by a clear history of parental syphilis, or a history of the presence of other typical lesions, would have established a positive diagnosis of congenital syphilis, but here there was no such supportive evidence.

Under such circumstances a therapeutic test is desirable, but all syphilologists of today wisely agree that it is, as a rule, inadvisable to give spirocheticides until a diagnosis of syphilis has been definitely made However, we felt justified in taking the responsibility of having a test made in this case because the appearance, location and tenderness of the lesion were characteristic of chronic perichondritis, and chronic localized perichondritis in this region is almost invariably syphilitic Moreover, delay was dangerous Suppuration, though not certain to follow a chronic hyperplastic tracheal perichondritis of this type, as it is in acute perichondritis, is always a serious matter in this location, because of the probability of mediastinitis and mediastinal abscess as a sequelae

We therefore supplemented the working diagnosis by making it *right laryngeal paralysis due to a small tumor-like mass involving the right tracheal wall, probably due to tardive congenital syphilis* Our colleagues in the Department of Syphilology concurred in our opinion and took charge of the case They administered neoarsphenamine intravenously starting with a dosage of 0.3 gm (5 grains) The result established the diagnosis of congenital syphilis The Wassermann test rose to 2 plus and later became doubtful After twelve weeks of the

neoarsphenamine treatment the tumor like swelling has flattened out and the tracheal rings have reappeared.

Comment—Some of the presented and many of the omitted features of this case are so well recognized and understood that comment may be limited to those features that are often overlooked

1 Palpation of the larynx and trachea is an important diagnostic procedure Palpatory search in the neck for nodes is routine, but the value of palpation of the laryngeal and tracheal cartilages is often overlooked.

2 A patient can have a good voice yet have a paralyzed vocal cord, even both cords may be paralyzed In most of such cases the voice is hoarse at the onset of the paralysis, but readjustment in time usually restores a good voice notwithstanding the fact that the paralysis is permanent The voice may be good with both cords paralyzed and the patient verging on asphyxia.

3 This child had a tumor-like mass of syphilitic perichondritis that pressed upon the right inferior laryngeal nerve, producing a paralysis of the right vocal cord In this connection it is well to recall that there are many different ways in which syphilis may produce hoarseness For example, there may be a gumma, abscess or ulcer in the larynx mechanically interfering with the cords More frequently the lesion is in the central nervous system, a meningitis, a gumma or a tabetic sclerosis, causing a paralysis of the vocal cords Most often the syphilitic cordal paralysis is due to compression of the recurrent nerve by an aneurysm, by lymph nodes a gumma, or as in this case, by a syphilitic tracheal perichondritis Though the symptoms may be entirely laryngeal, the causative syphilitic lesion may be in the brain the neck, or the chest.

As to *prognosis* of the laryngeal paralysis in this child, we may say positively that the paralyzed cord will never move again, no matter what treatment is used but this will not prevent the patient having a good voice because of the adjustment that has been made in cordal approximation

CHRONIC DISEASES OF THE NOSE, THROAT AND EAR

CLYDE A. HEATLY, M D , F A C S *

CHRONIC SINUSITIS

THE most common as well as the most difficult problems encountered in chronic nasal disturbances involve diseases of the nasal sinuses. Many significant advances have been made in recent years in the diagnosis and management of these disorders. The competent rhinologist has learned the importance of allergy in relation to chronic sinusitis from accumulated failures in cases in which this factor had been overlooked. He has also come to a better understanding of the physiology of the nose and thereby to a sounder appreciation of the value of carefully planned surgery which conserves rather than needlessly destroys nasal structures.

Classification of Sinusitis—Many classifications of chronic sinusitis have been suggested. It is perhaps simplest from the clinical standpoint to consider three groups: (1) chronic suppurative sinusitis, (2) chronic hyperplastic sinusitis, which is predominantly allergic, and (3) mixed forms in which a chronic infection has been superimposed on an underlying allergy. Allergy produces profound changes in the nasal and sinusal mucosa ranging from simple pallor and edema to extensive polypoid formation. These structural changes favor the stagnation of secretions by interference with ventilation and drainage and thereby promote the chronicity of secondary infections. It is now generally recognized that nasal polyps are a manifestation of chronic nasal allergy in most instances. Their well known tendency to recur, therefore, can be controlled only by appropriate management of allergy.

Diagnosis—1 A careful *history* is essential and should include questions directed to a possible underlying allergy. A family history of allergy is of great importance. The studies of Cooke and Vanderveer showed that, considering patients of all ages, about 60 per cent are sensitive with a unilateral family history and 67.5 per cent with a bilateral inheritance. In a group of 220 adult patients with nasal allergy reported by Hansel, 61.4 per cent gave a positive family history.

2 The *intranasal examination* should note the color of the mucous membranes (pale, water-logged, boggy tissues suggest allergy), the presence of septal deviations or polyps, and the position of purulent secretions with relation to the middle turbinate. It will be recalled in

From the Division of Otolaryngology, Department of Surgery, University of Rochester, School of Medicine and Dentistry, Rochester, New York.

* Associate Professor of Surgery, in Charge of Otolaryngology and Bronchoscopy, University of Rochester, School of Medicine and Dentistry, Otolaryngology-Rochester Municipal and Strong Memorial Hospitals.

this connection that the anterior group of sinuses (antra, frontals and anterior ethmoids) empty into the nose beneath the middle turbinate, while the posterior group (posterior ethmoids and sphenoids) drain above the posterior portion of this structure. The routine use of the nasopharyngoscope should be urged as part of this study.

3 The *transillumination test* is easily done by any physician and is of particular value in detecting changes in the maxillary sinuses.

4 *Study and culture of the nasal and sinus secretions*. Smears of the nasal secretions and sinus washings should be stained with eosin-methylene blue and studied for eosinophils. In the allergic nose free from infection a preponderance of eosinophilic cells may be demonstrated. In the presence of infection, however, these may be largely replaced by neutrophilic (acute infection) or lymphocytic (chronic infection) cells. In such cases it may be necessary to repeat the nasal smears carefully for several days before eosinophils are discovered. Hansel has repeatedly stressed the diagnostic value of the cytologic examination and it is now accepted as an important part of the study of these chronic nasal and sinus disturbances. The predominating organisms should also be learned by appropriate bacteriological examination.

5 *X-ray examination*. The correlation of well taken radiographs with the clinical and laboratory findings is of the greatest value in chronic sinusitis and should be done routinely in all difficult cases. This study may be further aided by the use of radiopaque substances introduced into the sinuses by cannula or by the displacement method.

Treatment—The limits of this paper do not permit a detailed summary of this important subject. This may be just as well since few experienced rhinologists are in complete agreement on many of the technical problems of management. A few general remarks, however, may be permitted.

1 Systemic factors involving general health, constitutional diseases and, in particular, allergic states must be appropriately controlled so far as possible. Remember that the allergic types of chronic sinusitis can never be controlled by local or surgical methods alone, and that many of our outstanding failures spring from a lack of appreciation of this fact.

2 Local mechanical factors which interfere with proper sinus drainage must be surgically corrected. These include deviations of the nasal septum, hypertrophied turbinates and polyps.

3 A period of conservative local treatment including irrigation of the affected sinuses or use of the Proetz displacement technique will cure many of the mild types of infection and is indicated in those cases where preliminary allergic study and treatment is to be carried out. The local use of sulfonamide solutions has not been of striking value in these chronic cases.

4 When it is at once or subsequently apparent that surgical mea-

ures are necessary for cure, *plan* the type of surgery to be tried whenever possible with careful thought to the restoration of a functioning nose. This may involve surgery for ventilation, surgery for drainage, or radical measures for the eradication of hopelessly diseased tissue. Proetz's dictum is worth repeating—"More surgery is almost never an improvement on too much surgery done before."

5 The exact limitations of intranasal and radical sinus surgery are controversial. For example, many experienced rhinologists will advise an intranasal window resection in cases in which others will feel that only radical antrum surgery will suffice. Careful consideration of all the clinical and x-ray findings in the *individual* problem is imperative.

6 Do not be too hasty in advising sinus surgery in asthmatic states. Although the literature contains many reports of striking improvement in asthmatics after radical sinus surgery, there is increasing evidence that such benefit is either temporary or limited to a small group of patients. It is my opinion that sinus surgery in asthmatics should be carried out only after a preliminary period of careful allergy management, and then only when there are pathologic changes in the sinuses that require operation on their own merits or where there is strong evidence of a causal bacterial relation.

CHRONIC TONSILLITIS

Pathology—The lymphoid structures of the throat include the adenoid tissue in the nasopharynx, the palatine tonsils, the lingual tonsils and scattered, irregularly developed masses on the lateral and posterior walls of the pharynx. All are similar in that they contain lymphoid tissue with germinal centers. The tonsils possess a well defined capsule which facilitates complete and permanent removal by proper surgical methods. The adenoids, however, are loosely formed without encapsulation so that recurrence after removal is commonly observed, particularly in early childhood when a strong tendency to compensatory hypertrophy exists.

A clear understanding of the histologic structure of these tissues is necessary to a proper appreciation of the many disturbances caused by chronic infection. The principal point of interest in this respect lies in the structure of the crypts. These are particularly well developed in the palatine tonsils where they are narrow, deep and ramified in contradistinction to the wide-mouthed, superficial and short crypts seen in the other lymphatic structures of the throat. The epithelium lining these crypts, notably in the palatine tonsils, contains a rich network of capillaries. We know from microscopic study that chronic infection results in ulceration and destruction of portions of this lining epithelium, thus producing a thrombosis of innumerable capillaries as well as many of the larger collecting veins which lie just under the epithelium. The mouths of such infected crypts are frequently closed

by the formation of scar tissue, thus intensifying the infection through lack of drainage. There are no mucous glands in these crypts to assist in the expulsion of bacteria and debris. The possibilities for dissemination of infection are further enhanced by the constant movements of the throat as well as by the compression incident to swallowing. It has been estimated that 75 per cent of all primary foci of infection occur in the mucous membranes of the head. The high incidence of chronic tonsillitis in this group can be easily understood in the light of these considerations.

There has been a decided tendency recently to discount the value of *tonsillectomy* and in fact to consider the whole relationship of focal infections greatly overemphasized. This can prove a healthy point of view if it prevents or even lessens indiscriminate surgery. The importance of the properly indicated and carefully performed tonsillectomy, however, is too thoroughly established to justify a hasty endorsement of this trend.

The Relation of Chronic Tonsillitis to Certain Systemic Diseases—1
Acute Glomerulonephritis—From the standpoint of etiology, two important clinical facts must be emphasized. (a) In a great majority of instances acute nephritis follows infections of the upper respiratory tract. (b) Careful bacteriologic and immunologic studies indicate that the hemolytic streptococcus is the chief offender. The removal of diseased tonsils is of great importance in many of these cases. The time for operation should be determined by the internist and is as a rule after the general manifestations of the nephritis have disappeared. Acute exacerbations frequently follow such surgery, but usually subside within a short period.

2 *Acute Rheumatic Fever*—Rheumatic fever in well over 50 per cent of cases is preceded by a sore throat or tonsillitis. Accumulated experience on the effects of tonsillectomy in this disease may be briefly summarized as follows. (a) It occurs from 25 to 35 per cent less often in tonsillectomized children. (b) When a rheumatic infection has once manifested itself, however, tonsillectomy does not safeguard the child against recurrent attacks nor against carditis.

3 *Arthritis*—Certain forms of arthritis, notably of the infectious or rheumatoid group, seem to be definitely associated with focal infection and are often promptly relieved when the focus is removed. Needless removal of questionable foci should be avoided, especially in the hypertrophic or degenerative groups.

4 *Allergy*—It is generally agreed that tonsillectomy does not aid in improving the effects of treatment of respiratory allergy in most instances. Statistics show that nasal or pulmonary allergy may occur with the same incidence in the tonsillectomized and nontonsillectomized groups. When tonsillectomy is indicated it is particularly important to avoid the stage of active allergic symptoms. Patients who

are allergic or who give a positive family history of allergy should not be operated on during the hay fever season because of the danger of inducing bronchial or nasal allergy. Finally, all cases of allergy should be under control before resorting to surgery.

5 *Poliomyelitis*—Evidence has accumulated suggesting that there is a causal relationship between the removal of tonsils and the onset of bulbar poliomyelitis within the time interval corresponding to the incubation period of the disease. While this connection cannot be considered established at the present time in view of the conflicting opinions of competent observers, it would nevertheless seem prudent to avoid tonsillectomy when this disease is prevalent.

THE CHRONIC EAR

The chronic ear is often bred of neglect and fostered by it. Recent advances in the management of acute aural infections by the intelligent use of chemotherapy may be expected to reduce the incidence of chronic suppuration. It must be emphasized, however, that certain cases of acute otitis, especially those complicating scarlet fever, measles, diphtheria and tuberculosis, have strong chronic tendencies from the onset due to their necrotizing effects on the drum and mucous membranes of the middle ear, as well as to the early bone involvement which frequently follows. The attention of both the physician and the patient is often centered on the mere nuisance of the chronic otorrhea without any thoughtful consideration of the potentially serious complications which may develop. The certain progressive loss of hearing, the possibilities of systemic disturbances from a chronic focus, and finally the constant menace of a sudden serious or fatal intracranial invasion make imperative a careful study of the individual case rather than the routine employment of antiseptic drops and a defeatist attitude.

1. *The Location and Significance of the Perforation*—Two general groups of perforations occur, the central and the marginal. The most meticulous cleansing of the external canal and drum may be necessary to establish this important distinction. The *central perforation* occurs in the membrana tensa and, as the name implies, does not involve the margins of the drum. It is frequently seen in the lower anterior quadrant of the drum as the result of a chronic tubotympanic infection. A large kidney-shaped perforation occupying the lower half of the drum is another common variety. A central perforation is rarely accompanied by necrosis of the bony walls of the tympanic cavity or of the ossicles, and may be properly classified as the *nondangerous form* of chronic otitis.

The *marginal perforation*, on the other hand, must be viewed as an indication of a potentially *dangerous form* of aural suppuration. This type of perforation may appear in variable form, size and location,

but, by definition, shows destruction of the periphery of the drum and the annulus tympanicus. A particularly dangerous form of marginal perforation occurs in the *membrana flaccida* (Shrapnell's area) and is commonly referred to as an *attic* perforation. Perforations of this type may be small, concealed by a dry adherent crust, and easily overlooked by a casual inspection of the drum. They must be considered the most dangerous type of drum perforations because they indicate suppuration of the attic and tympanic antrum, caries of the incus, and a strong probability of cholesteatomatous formation. Total loss of the *membrana tensa* or drum proper should be considered as marginal perforations.

2 **Cholesteatoma**—The formation of cholesteatoma occurs in approximately one third of all chronic infections of the ear. Primary cholesteatoma is rare. The so-called secondary or common type follows perforations of the marginal or attic variety—never central perforations. It is caused by an extension of the squamous epithelium of the external canal and tympanic membrane into the middle ear and as such represents a reparative attempt by nature to cure the suppuration. The cholesteatoma consists of a matrix attached to the bony walls of the tympanic antrum or attic from which masses of squamous epithelium are cast off. The layers of epithelium accumulate and the desquamated masses of epithelial cells are trapped within the bony confines of the tympanic spaces so that a gradually expanding type of tumor is produced. As a result, pressure erosion of surrounding bony structures takes place and invasion of the facial nerve, labyrinth (especially by way of the exposed horizontal canal), or adjacent dural surfaces frequently follows. Such serious complications commonly occur as the result of an acute exacerbation of the chronic suppuration during an acute upper respiratory infection or following swimming.

The cholesteatoma grossly may present a smooth, glistening appearance or in septic cases may resemble a mass of putty. Its odor is characteristically foul. On microscopic study it is found to consist of masses of desquamated epidermis and cholesterol crystals caused by the decomposition of organic matter in the absence of oxygen. In examining a case for the presence of cholesteatoma, material may be secured for microscopic study by passing a small bent cotton applicator through the perforation into the attic region or by gently douching with 50 per cent alcohol through a slender attic cannula. Greasy, foul scales resembling onion skin will be observed floating on the surface of the returned solution. It must be emphasized that many cases of cholesteatoma may remain relatively dormant for many years, with scanty or completely overlooked aural discharge. Such cases are particularly dangerous because the presence of this serious complication is frequently unsuspected until sudden manifest evidences of extension

arise The formation of cholesteatoma may be small, limited to the middle ear or attic, or be of enormous size, destroying and occupying most of the mastoid process

3 Aural Granulations and Polyps—Granulations are commonly encountered in all forms of chronic otitis and may arise from any portion of the tympanum or attic They consist of soft, red, easily bleeding tissue and as such are readily identified Polyps may arise from the infected mucous membranes or from granulation tissue itself They vary greatly in size and appearance Many cases are seen in which a large polyp fills the entire external auditory canal It is important to emphasize that, while polyps may arise from the ossicles, edges of the drum or any portion of the bony wall, they are commonly attached to the wall of the labyrinth itself In such instances, removal may precipitate a sudden, overwhelming labyrinthine infection with rapidly fatal meningitis

It is important to counsel the practitioner against careless removal of aural polyps If removal is attempted, the base of the polyp should always be cut through clearly with the aural snare, exercising great care to avoid traction In cases of acute exacerbation of a chronic infection with headache, slight vertigo and obstruction to drainage by a large polyp of the canal, the situation calls for immediate radical mastoidectomy, and the physician who attempts to improve drainage by removal of the polyp alone risks a serious complication It is imperative to conduct careful preliminary studies of labyrinthine function in all cases of aural polyps

4 X-ray Studies—It is important to obtain complete x-ray studies in all cases of chronic aural suppuration of the so-called dangerous variety Nevertheless, it should be pointed out to the practitioner that such studies are seldom as informative as in acute conditions, usually showing a generalized sclerosis in a poorly developed or infantile type of mastoid Occasionally, however, areas of erosion may be identified, especially in cases of cholesteatoma X-rays should be routinely obtained before undertaking radical mastoid surgery

5 Treatment—Nondangerous Chronic Otitis—Chronic infections involving the sinuses or lymphoid structures of the throat must be cleared In selected cases, particularly in childhood, the direct application of radium to the eustachian orifices has proved of value Careful systematic cleansing of the tympanic cavity followed by insufflation of antiseptic powders, such as boric-iodine (Sulzberger formula) or sulfonamide mixtures, is indicated Irrigation of the attic by means of a suitable cannula is an effective procedure especially where the perforation is large or in the upper posterior portion of the drum Alcohol in 50 per cent solution is suitable for this purpose Antiseptic drops such as alcohol (50 per cent) or boric acid (20 grains) in alcohol may be prescribed for home use

Dangerous Type of Chronic Otitis—These cases are as a rule best managed by appropriate surgical measures. This is particularly true in the presence of a complicating cholesteatoma. The radical or modified radical operation is generally necessary. The attention of the surgeon should not be distracted by efforts to conserve the already impaired hearing in these dangerous infections. His primary consideration should be meticulous complete removal of the infection. Many of the failures after surgery result from a disregard of this important principle. As a matter of record it should be noted that the hearing may be slightly improved as well as decreased, in about equal proportions after radical surgery.

THE TREATMENT OF DEAFNESS IN CHILDHOOD BY IRRADIATION

Most physicians are aware of the fact that enlarged adenoids are at the root of the majority of ear disorders in childhood. The consequent partial or complete blockage of the eustachian orifices frequently results in an insidious slowly progressing deafness recurring attacks of acute middle ear suppuration or a persistent chronic otorrhea of the nondangerous variety. It is not so commonly realized that recurrence is exceedingly common after adenoidectomy before the age of puberty (in fully 75 per cent of cases according to Crowe) and that this recurrence or compensatory growth is frequently around the eustachian orifices where complete surgical removal is difficult or impossible because of possible damage to those important structures. The resulting tubal obstruction over a period of time causes disturbances in the mucous membrane of the middle ear, varying from early hyperemia and secretory changes to the formation of a myxomatous or fibrous tissue which interferes with the mobility of the ossicles.

While the physician may suspect a hearing disturbance from otoscopic evidence of retraction of Shrapnell's membrane or of the entire drum, only careful audiometric studies will show its true proportions. The earliest changes are in the high tones between 10 000 and 16 000 double vibrations, which are far above the speech range but as the mucous membrane changes progress the tones within the speech range gradually become involved. This impaired hearing for high tones with good hearing for low tones is the earliest symptom of middle ear deafness in childhood. Although apparently contrary to the classical dictum in otology that such high tone loss indicates an inner ear or nerve lesion the extensive investigations of Crowe and his associates have established it as a clinical fact.

The possibilities of reducing the size of lymphoid tissue and temporarily inhibiting its growth by irradiation in doses too small to injure surrounding structures have been known for many years. Crowe and Burnham first made extensive clinical use of radon applied by means of a special applicator passed through the nose to the region of the

eustachian orifices Their success in so treating these cases of middle ear deafness in childhood has prompted others to employ a similar method, using radium rather than radon

The writer and his associates in 1942 reported* on the successful use of a special applicator holding two 12.5 mg radium needles in its head The use of two such applicators, using a total of 50 mg of radium, permits the treatment of both eustachian orifices in twelve minutes, delivering a dose of 5 milligram hours to each orifice Such a short treatment time with this small amount of radium is made possible by the fact that a high proportion of beta radiation is used in actual contact with the area to be treated The applicators are small and can be introduced in most children under local anesthesia An interval of three months is usually allowed before a second irradiation is given This dosage is far below the amount of radium which could cause any injury to the mucous membranes and surrounding structures The results have fully substantiated the successes reported by Crowe and his associates The physician who is alert to the frequency of deafness in childhood and its common cause may thus render a valuable service in preventing the establishment of permanent changes

THE TREATMENT OF BRONCHIAL ASTHMA AND OTHER CHRONIC PULMONARY DISEASES ACCOMPANIED BY CONSTRICTION IN THE BRONCHIAL PASSAGEWAY

ALVAN L. BARACH, M.D., F.A.C.P.*

THE treatment of bronchial asthma is generally presented from two points of view (1) investigation of the allergic factor through the use of the skin test work-up, elimination diets and removal of or desensitization against the offending substance, and (2) palliative treatment, including drugs which produce temporary relief of bronchial spasm, such as epinephrine and aminophylline. Despite this combined therapeutic endeavor, many patients with bronchial asthma suffer from recurrent and more or less severe bronchial spasm. In some instances, pulmonary overdistention is followed by varying degrees of invalidism or by emphysema of the lungs.

The purpose of this clinic is to present a method of treatment that is based neither on the allergic nor palliative approach but rather on an understanding of the pathological physiology of bronchial spasm as it affects the lungs and mucous membrane of the small bronchioles. The principle involved in this physiologically directed therapy may be described as "repeated bronchial relaxation."¹ The administration of adrenalin produces a temporary relief from bronchial spasm, but repeated injection is not followed by a progressive relaxation of the bronchial spastic muscle. On the contrary, the patient with asthma frequently becomes less and less responsive to epinephrine, either by injection or by inhalation, and a state of intractable asthma or even status asthmaticus may take place.

In using the phrase "repeated bronchial relaxation," I refer to a cumulative relaxation of the circular muscle that surrounds the intrathoracic bronchi and bronchioles, which ultimately results in a continuously patent passageway into the lungs, i.e., a remission of the symptoms of asthma. Although this principle of treatment first became apparent as a consequence of intermittent inhalations of helium-oxygen mixtures, repeated bronchial relaxation may now be more simply obtained in many cases without the use of helium therapy. In patients who do not respond satisfactorily to the simplified program of bronchial relaxation, the inhalation of helium with oxygen may be necessary to secure a good remission from the symptoms of the disease.

From the Department of Medicine, College of Physicians and Surgeons, Columbia University, and the Presbyterian Hospital, New York City.

* Associate Professor of Clinical Medicine, College of Physicians and Surgeons, Columbia University; Assistant Attending Physician, Presbyterian Hospital.

Following the discussion of the pathological physiology of severe asthma, I will, therefore, outline a program that may be carried out in the absence of helium-oxygen therapy, and one that includes the administration of this lighter-than-air gas where facilities for its effective administration are present. Either regimen may be carried out in the hospital, home or office, although the administration of helium by hood is more practical in a hospital with trained personnel.

PATHOLOGICAL PHYSIOLOGY OF OBSTRUCTIVE DYSPNEA

An understanding of the disturbed mechanics of respiration in obstructive dyspnea will be of help in carrying out therapeutic procedures which are based on the physiological state of severe asthma. When an obstruction is experimentally produced in an animal by decreasing the diameter of the larynx to one-third the normal lumen, the first effect observed is the increased effort on the part of the respiratory musculature to draw air into the lungs. Measurement of the intrapleural pressure reveals an immediate increase in negative pressure during the act of inspiration, in expiration the intrapleural pressure approaches the atmospheric pressure. The consequences of obstruction during inspiration can be separated from the effects of obstruction during expiration. When inspiration is allowed to proceed normally but expiration is conducted through a constricted orifice, an increased effort on the part of the animal is observed during expiration, accompanied by a change in intrapleural pressure toward that of the atmosphere during the expiratory cycle. The intrapleural pressure during inspiration is unchanged, and at the end of five hours a dog shows no progressive increase in dyspnea.

When expiration is allowed to proceed normally but inspiration is conducted through a constricted orifice, however, a progressive increase in negative intrapleural pressure takes place during the inspiratory cycle. This is accompanied by more and more severe dyspnea, edema of the lungs and death of the animal. Although autopsy of dogs who exhaled against a localized obstruction (or positive pressure) showed little or no change in the lungs as long as inspiration was allowed to proceed normally, the pathological anatomy of animals subjected to resistance during inspiration (or comparable negative pressures) was that of pulmonary congestion and edema, more marked in the dependent portions of the lung, with areas of emphysema at the periphery.^{2,3,4} We are, therefore, confronted with the basic pathophysiological factor in obstructive dyspnea, namely, that elevated negative pressures within the chest during the inspiration result in extensive damage to the lungs. The mucous membrane of the medium and small intrathoracic bronchi are likewise exposed to a negative pressure which exerts a cupping action on them, resulting in congestion and edema, as well as increased formation of mucus. This

swelling of the mucous membrane, as well as the production of increased expectoration, increases the degree of obstruction and affords an explanation for the fact that bronchodilatory drugs may not always result in prompt disappearance of the symptoms of obstructive dyspnea.

An additional consequence of the elevated negative intrapulmonary pressure is to increase the inlet of blood into the right heart but retard the exit of blood from the lungs. During expiration against resistance, the flow of blood into the right auricle is accomplished by a compensatory rise in systemic venous and arterial pressures. If expiratory obstruction is so severe as to result in a marked increase in intrapulmonary pressure, the total cardiac output may be decreased. The preponderant effect of obstructive dyspnea in both cycles of respiration is that of congestion and edema, both in the alveoli and in the mucous membrane of the smaller bronchi. This is due to the pathologically elevated negative pressure in the lungs during inspiration although opposed by the relative increase in positive pressure during expiration.

When obstructive dyspnea is due to constriction in the extrathoracic trachea or larynx, inspiration and expiration are approximately equally prolonged. The instantaneous increase in pulmonary ventilation is stimulated by proprioceptive reflexes in the lungs. Dyspnea is then aggravated by accumulation of carbon dioxide and anoxia due to pulmonary congestion, edema and irregular incomplete ventilation of the alveoli, which impairs diffusion of oxygen into the blood. In the early stages of obstructive dyspnea, increased ventilation may result in a blowing off of carbon dioxide with a slight shift in pH toward the alkaline side but as pathological changes occur in the lungs the efficiency of carbon dioxide elimination is impaired and carbon dioxide retention may be accompanied by an alteration in acid base equilibrium toward the acid side. It must be borne in mind, however, that an elevated carbon dioxide content in the arterial blood and the alveolar air makes possible a larger excretion of carbon dioxide per unit volume of breathing, which tends to retard the development of an uncompensated acidosis.

When obstruction takes place within the chest, expiration is prolonged, due to the fact that intrathoracic bronchi enlarge during inspiration and constrict during expiration. Under these circumstances, a forcible inspiration will result in the passage of air through an area of bronchial narrowing into the alveoli the walls of which are subjected to an increased negative pressure. During expiration the volume of the chest is diminished and the bronchioles are constricted so as to hinder the exit of air from the alveoli. The succeeding inspiration draws additional air into the distended alveoli and further pressure is placed on the thinned-out walls, resulting in impairment of capillary

circulation and at times in rupture of the wall. The duration of expiration in patients with asthma (or obliterative bronchiolitis) may be two to three times longer than inspiration, since an approximately equal volume of air is delivered through tubes that are about 30 per cent smaller in diameter during the expiratory cycle and because inspiration is achieved by the employment of higher pressures than expiration. Acute attacks of dyspnea, brought on either by bronchial spasm or exercise, may result in a temporary overdilatation of the lung alveoli because of this impaired mechanism of emptying. Although the intrathoracic bronchial passageway in normal individuals shows an increased diameter during inspiration and narrowing during expiration, the degree of expiratory bronchial constriction in patients with asthma may be very marked, as has been observed during bronchoscopic examination. The use of positive pressure in inhalational therapy has the advantage of maintaining a more patent lumen during expiration,⁵ as well as combating pulmonary edema⁴ and decreasing inspiratory dyspnea.⁶

The use of helium was introduced by the author for the treatment of obstructive dyspnea only.^{7, 8, 9} During quiet breathing the substitution of helium for nitrogen results in no change in the effort of respiration. Since, however, the velocity of movement of a gas through a constricted orifice is inversely proportional to the square root of the density of the gas, the pressure required for the movement of an 80 per cent helium 20 per cent oxygen mixture past the point of localized obstruction is almost one-half that required to breathe oxygen or air. If the constriction in a tube were to be continued in a linear direction, no decrease in pressure would be manifested when a helium-oxygen mixture was substituted for air, since the viscosity of helium is, in fact, slightly higher than nitrogen. In urgent dyspnea, however, even without localized obstruction, a smaller pressure will yield a larger pulmonary ventilation when helium-oxygen mixture is substituted for air. During the inhalation of a helium-oxygen mixture in patients with respiratory obstruction, the negative pressure during inspiration is diminished by the inhalation of 80 per cent helium with 20 per cent oxygen. Furthermore, a swifter and more complete emptying of the lung air has been shown when the helium-oxygen mixture was inhaled. In many instances the volume of breathing in the presence of wheezing respiration is diminished 25 per cent when 80 per cent helium with 20 per cent oxygen is substituted for either air or pure oxygen.

CLINICAL RESULTS OF HELIUM-OXYGEN THERAPY

When helium-oxygen therapy was first used in the treatment of status asthmaticus, the inhalation of this lighter-than-air gas was kept up for a period of two to five days. In other patients with intractable asthmas, inhalation of helium with oxygen was conducted for two

hours twice a day. It was soon observed that the majority of patients treated in this way were relieved of asthma for a considerable period of time thereafter. In a series of eighty-four previously reported cases of status asthmaticus and intractable asthma, inhalation of helium-oxygen mixtures was followed by complete freedom from asthma or exceedingly mild asthma in forty instances, in thirty-six cases a marked alleviation of the symptoms of asthma took place with the restoration of sensitiveness to adrenalin, in the remaining eight cases improvement was either very slight or transient. In thirty patients in this series in whom follow-up observations could be made, fifteen maintained either all or a substantial part of their improvement for six months or more.^{10 11}

The mechanism of improvement was traced in part to the local relaxation which repeated inhalation of the helium-oxygen mixture produced, in addition, the mucous membrane in the bronchioles was not exposed to the pathologically elevated negative pressure during the inspiratory cycle, which tended to diminish the congestion, edema and the production of mucus, which was previously shown to be produced by a maintained negative intrapulmonary pressure. One of the advantages of a less effortful type of breathing appeared to be the general feeling of relaxation induced by alleviation of the dyspnea itself. Additional bronchial relaxation may take place as the result of efferent impulses from the cerebrum.

The value of relieving tension in the central nervous system is shown by the frequent beneficial response to injection of morphine, or preferably dilaudid. Although repeated injection of morphine in the treatment of asthma is unwise, since the drug is habit-forming and because respiratory depression may ensue, the administration of small doses for a limited period is completely justified and often of great value. The point of the present appraisal of the use of dilaudid is to emphasize its usefulness as part of the program of repeated bronchial relaxation, which will be described in detail later.

PHYSIOLOGICAL ADVANTAGES OF REPEATED INJECTION OF AMINOPHYLLINE

Since it had been observed that repeated inhalations of helium with oxygen resulted many times in a remission of the symptoms of severe asthma, this principle was extended to the use of aminophylline. In many clinics the effective administration of helium therapy cannot be undertaken because of lack of equipment or trained personnel. The substitution of repeated injection of aminophylline for helium-oxygen inhalation may be carried out in many cases and an excellent clinical result be obtained. A program of combined helium-oxygen inhalation and aminophylline therapy has been previously reported in forty-six hospital patients in whom disappearance of asthma or exceedingly mild asthma, resulted in thirty-four cases with restoration of epineph

rine sensitivity and moderate asthma in nine cases. In fifty-four courses of this type of therapy in ambulatory or office patients, disappearance of asthma, or exceedingly mild asthma, took place in twenty-three instances, with restoration of epinephrine sensitivity with moderate asthma in seventeen cases. The duration of improvement in ninety-one courses of this type of therapy, including both hospital and ambulatory cases, was over one year in fifteen patients, from five to twelve months in twenty, and from one to four months in twenty additional cases.¹

The demonstration that intravenous injection of aminophylline (theophylline ethylenediamine) was of great value in the treatment of patients who had become refractory to epinephrine should be considered a milestone in the treatment of severe asthma.^{12, 13} This drug results in a lowering of venous and intrathecal pressures, dilatation of the coronary artery, stimulation of respiration and an increase in the total volume of blood flowing through the pulmonary circulation.¹⁴ Experiments on the excised lung suggest that the action of aminophylline is directly on the bronchial musculature, since the drug under these conditions also causes a relaxation of the spastically contracted bronchial circular muscle and thus re-establishes the normal diameter of the bronchus.¹⁵

Since the program of repeated bronchial relaxation calls for administration of aminophylline twice daily for a period of one week and then once daily for a period of one to two months, the intravenous route of administration did not appear practicable. Fortunately, the rectal instillation of 0.6 gm of aminophylline in 20 cc of water generally resulted in a degree of relaxation that was almost as complete (although not as prompt) as intravenous injection of 0.48 gm of the drug.¹⁰ In addition, the dizziness and palpitation at times occurring after intravenous injection do not take place, except very rarely, when rectal instillation is used. Oral administration of aminophylline does not usually terminate severe asthma, although giving the drug by mouth is effective when the symptoms are of mild or moderate intensity. Repeated intramuscular injections are impractical because they produce considerable soreness in the gluteal region. A conspicuous advantage of rectal instillation is that the patient is readily taught to employ the procedure himself at home.

IODIDES, GLUCOSE, COLONIC ETHER

We will now mention several other remedies that are useful in the treatment of intractable asthma. In some patients in whom bronchial spasm recurs with considerable severity and frequency, additional relaxation may be accomplished by rectal instillation of 50 to 90 cc of ether mixed with equal parts of olive oil.¹⁶ At times it is necessary to obtain a degree of relaxation comparable to that required in surgical

anesthesia, and when that is the case the procedure may be carried out under the supervision of an anesthetist. A partial or a complete remission in the symptoms of the disease may result. Other sedative drugs may be employed by rectum, such as paraldehyde, 20 cc. mixed with an equal quantity of olive oil. Both ether and oil and paraldehyde may be repeated two or three times in cases unresponsive to aminophylline therapy. Sedation is aided in apprehensive cases by repeated injection of dilaudid, $\frac{1}{32}$ grain, at eight- to twelve-hour intervals for two or three days, when oral or rectal use of this drug is insufficiently effective.

In a few cases the development of a slight fever may be followed by bronchial relaxation. This may be conveniently initiated by triple typhoid vaccine administered subcutaneously.

The intravenous injection of 50 cc. of 50 per cent glucose every day or every other day for three or four times has clinically been found helpful in certain cases. An explanation for the good results sometimes obtained by the injection of this hypertonic solution may be the withdrawal from the bronchial mucous membrane of local edema. It is also possible that other effects may be involved, such as a lowering of serum potassium.¹⁷

Patients with severe asthma appear to be almost uniformly benefited by the administration of potassium iodide, both during the state of continuous wheezing respiration as well as during the intervals between attacks. This drug not only stimulates the flow of mucus from the nose, throat and bronchial mucous membrane, but it seems to possess almost a specific effect in making less likely a recurrence of symptoms.

We have tried residence in filtered air chambers for ten years in the treatment of intractable asthma, with generally disappointing results. The value of filtered air is manifested in those cases in which pollen sensitivity is unquestionably present. In an individual who has hay fever and bronchial asthma the provision of filtered air would provide symptomatic relief by removal of the offending pollen. In some patients in whom intractable asthma has been provoked by pollen the symptoms may persist for a prolonged period of time unless a program of bronchial relaxation is pursued.

ADMINISTRATION OF OXYGEN

Administration of oxygen is generally indicated in cases of status asthmaticus, since removal of anoxia may prevent cardiorespiratory failure and decrease the effort of breathing by lowering the pulmonary ventilation. Furthermore, when sedative drugs are used continuous oxygen inhalation overcomes the anoxia which might otherwise be produced by substantial decrease in the volume of breathing. An oxygen tent or a nasal catheter is generally preferable to a face mask since

continuous therapy is more comfortably provided by these methods. If a face mask is employed, a high flow of oxygen, 6 to 10 liters per minute, may be required in the BLB apparatus¹⁸ to prevent the patient from inhaling air through the sponge rubber discs, i e., to prevent negative pressure developing in the mask. In the Meter mask¹⁹ the mixture of oxygen and air is made by an injector attached to the oxygen tank, which provides a high flow of an air-oxygen mixture with minimal resistance. The meter may be set at 40 to 95 per cent oxygen as required.

In cases of status asthmaticus the patient is placed in 50 or 60 per cent oxygen in a tent, or one of the other simpler methods referred to above is used, in the intervals between helium-oxygen treatment. In the absence of helium therapy the administration of oxygen should be continuous, generally in a concentration of 50 per cent, until the patient is out of danger. We have as yet found no indication for the employment of carbon dioxide in bronchial asthma, although this gas is said to act as an expectorant.²⁰ However, potassium iodide is from long experience a more dependable drug. In most cases of asthma the expectoration is the result of the negative pressure induced by bronchial spasm, although it often seems to the patient that mucus is the cause of the attack. In many cases, however, an accumulation of mucus during the night takes place and must be expectorated in the morning to provide a clear airway. To accomplish this purpose the inhalation of the nebulized spray of 1:100 epinephrine is the most satisfactory procedure.

INHALATION OF 1 PER CENT EPINEPHRINE AND 1 PER CENT NEOSYNEPHRIN

Inhalation of 1:100 adrenalin, produced by a satisfactory nebulizer, has decisive advantages over subcutaneous injection in most patients, since a relatively small amount of the drug is thereby absorbed and systemic effects consequently not produced.* In patients who have

* The nebulizer employed in our investigations during the past five years has been that made by the Vaponefrin Company. In this nebulizer the solution is thrown, either by the pressure of the hand bulb or by a stream of oxygen from a cylinder, against a glass baffle plate which breaks up the epinephrine solution into a fine suspension. This can be observed floating in the air for a perceptible interval after it has left the nebulizer and for this reason may be expected to reach the smaller bronchi. The epinephrine employed for nebulization has been that contained in vaponefrin solution, which has been described as racemic methylamino-hydroxy-ethyl-dihydroxy-benzene hydrochloride.²¹ Vaponefrin solutions have been found more stable than epinephrine solutions when stored under similar conditions, and retain their pressor potency when discolored.²¹

We have observed no irritative effects from the use of vaponefrin solution in moderate amounts over periods of three years. When patients employ the spray excessively, drying of the throat and larynx may take place, but even under these circumstances no lasting harmful effects have been noted. It should be emphasized that use of vaponefrin or epinephrine many times during the day and night is bad practice since progressive refractoriness to the drug is thereby promoted, and

abrupt severe paroxysms, hypodermic administration of adrenalin may at times be necessary until progressive bronchial relaxation has been accomplished. However, it has become apparent from observation of many cases of status asthmaticus that frequently repeated injections of adrenalin lead to a progressively more severe state of bronchial spasm. It should be recognized that, when adrenalin is repeated three to six times a day, the condition of the patient may get worse even in the presence of a program of bronchial relaxation. The reason for this is not clear but the fact that it does take place in certain patients is unquestionable. Secondary vasodilatation of the mucous membrane of the bronchi may be involved. Attempts should, therefore, be made to discontinue hypodermic adrenalin medication at the onset of the regimen of repeated bronchial relaxation, and to employ the inhalation of vaponefrin or epinephrine at such intervals as may be required by acute paroxysms of wheezing or coughing.

TECHNIC OF TREATMENT

Aminophylline—If aminophylline is prescribed *intravenously* it is better to give 0.48 gm. than 0.24 gm. Since the latter dosage occurs in a 10-cc ampule, the physician is frequently tempted to employ the smaller dosage. However, much more complete and lasting relaxation will occur when two ampules are used. Dizziness, palpitation and feelings of faintness should be avoided by taking the precaution of administering the solution slowly, i.e., in an eight-minute period.

When aminophylline is given *by rectum* it is highly desirable to follow out the method we have advocated. Powder (or capsules) of the drug should be on hand containing 0.5, 0.6 and 0.7 gm. of aminophylline. For patients in the lower weight classification the smaller dosage 0.5 gm., is employed, for persons of moderate weight, such as 150 pounds a dose of 0.6 gm., and for patients in the neighborhood of 180 pounds or over, 0.7 gm. may be used.* The powder is placed in a receptacle containing 20 cc. of lukewarm tap water and gently stirred for half a minute. A No. 10 French rubber catheter is thoroughly greased with KY jelly and passed into the rectum for a distance of approximately 3 to 4 inches. The aminophylline solution is then drawn up into a 20-cc syringe and the solution injected through the catheter. The open end of the catheter has to be cut off so as to make a tight fit between the syringe and the catheter. It is preferable although not necessary for the patient to rest for an hour after the injection. The reason for rehearsing this procedure in detail is that the employment of an enema tube may not only be irritating but is often responsible for

In many patients who weigh between 110 and 150 pounds, 0.7 gm. may be necessary to produce bronchial relaxation, even if nausea and vomiting result.

increasingly severe asthma may result. When attacks of wheezing respiration recur at increasing frequent intervals despite inhalation of adrenalin, a program of bronchial relaxation should be instituted by one of the methods described.

opening up the anus to such an extent as to result in subsequent leakage of the solution into the bed

Helium-Oxygen Therapy—When helium-oxygen therapy is administered in a helium hood, a positive pressure of 4 cm of water is generally employed.^{22 23} The pressure may, however, be varied from 1 to 6 cm, the higher pressures being more effective in terminating inspiratory dyspnea, since the helium-oxygen mixture is gently pushed into the lungs under these circumstances. The hood should be used with the new soft rubber collar that has an upward extension around the neck approximately 3 inches long*. A flow of 2 to 3 liters per minute of the helium-oxygen mixture, with 0.5 to 1 liter of oxygen, will maintain a positive pressure if the collar is suitably adjusted. Unless a specially trained technician or doctor is available, helium-oxygen therapy cannot be effectively administered in a positive pressure hood.

If the Meter mask is employed, the inspiratory valve is removed and a flow of 6 to 8 liters of an 80 per cent helium 20 per cent oxygen mixture is administered, depending upon the weight of the patient and the degree of dyspnea. It is desirable to connect the helium-oxygen cylinder with an oxygen tank by a Y tube and administer 1 to 2 liters of oxygen if the patient has pulmonary emphysema, or even functional pulmonary overdistention, either of which is generally manifested by cyanosis†. When the regulator is set at a given flow, such as 7 liters per minute, it must be borne in mind that the actual flow when a helium-oxygen mixture is used is 1.7 times the indicated rate. These high flows are relied upon to prevent excessive accumulation of carbon dioxide in the large latex bag. When the Meter mask is used for helium-oxygen therapy, the meter should either be removed and a water bottle substituted for it, or it should be filled one-third full with tap water to provide adequate humidification. If the B L B mask is employed, similar flows of the helium-oxygen mixture are used. It should be remembered that the flow of the helium-oxygen mixture is to be maintained sufficiently high to prevent the necessity for drawing air through the sponge rubber disk in the B L B apparatus.

CHRONIC BRONCHITIS AND OTHER CHRONIC PULMONARY DISEASES ACCOMPANIED BY CONSTRICTION IN THE BRONCHIAL PASSAGEWAY

In many chronic affections of the lungs, such as chronic bronchitis, obliterative bronchiolitis, bronchiectasis, pulmonary emphysema and pulmonary fibrosis, varying degrees of constriction in the respiratory passageway may be present. In some cases infection is responsible for inflammatory swelling of the mucous membrane, in others bronchial

* This may be obtained from the Oxygen Equipment Manufacturing Co., 405 E. 62nd St., New York, N. Y.

† It is frequently more convenient to employ a tank of 25 per cent oxygen 75 per cent helium than to use a separate oxygen and helium-oxygen cylinder.

spasm is intermittently found. The principles of bronchial relaxation described above may be utilized in securing a more patent bronchial passageway in these illnesses. Since the clinical entities referred to are chronic in a more continuous sense than bronchial asthma, neosynephrin has the advantage of a drug that does not develop refractoriness, such as may happen with frequently repeated use of adrenalin. Neosynephrin is admittedly a poor bronchodilator but its vasoconstrictive action is more prolonged than that of adrenalin and is not apt to result in secondary vasodilatation. Inhalation of the nebulized spray of 1 per cent neosynephrin two to three times daily is frequently helpful in increasing the patency of the bronchial passageway. Although this may be given by a handbulb it is often preferable for the patient to purchase a regulator and nebulize 0.5 cc. of the 1 per cent neosynephrin solution by means of an oxygen flow of 4 to 5 liters per minute. In this way a more adequate dosage of the drug is obtained, there are no side reactions to this medication. Inhalation of small amounts of epinephrine, or vaponefrin, by handbulb, or 0.25 cc. by oxygen spray, may also be used two or three times daily, frequently with considerable subjective relief of dyspnea. Excessive use of the drug must be guarded against.

In the course of any of the above-mentioned chronic diseases of the lungs, acute infection may usher in a state of intractable bronchial spasm. Under these circumstances all the measures outlined for the treatment of bronchial asthma may be employed. The continuous inhalation of oxygen-enriched atmospheres is of crucial value in acute respiratory insufficiency caused either by infection or overexertion. After one to two or three weeks, the concentration of oxygen should be *gradually* lowered to that of the atmosphere. The nasal catheter is almost essential for a slow reduction in the oxygen percentage of the inhaled atmosphere. This may require two to three weeks. Nasal oxygen may be begun at 5 liters per minute, and the flow diminished 0.5 liters every day. The patient may then develop a remarkable adaptation to a sea level atmosphere, although some dyspnea may persist, especially on exertion.¹¹ In some patients with pulmonary fibrosis and pulmonary emphysema, the inhalation of 70 per cent oxygen for one-half an hour morning and night may be provided by the Meter mask. This results in a partial and temporary but still useful decrease in pulmonary distention in those cases in which an oxygen debt is present.

Each case of chronic pulmonary disease requires an individual appraisal of the pathological physiology involved in his condition. Chronic infection in the bronchi may be treated by chemotherapy when the organisms that are responsible for the condition have been determined to be those which respond to the sulfonamide drugs or to penicillin. Inhalation of the nebulized spray of sulfadiazine in 2.5 per cent ethanolamine solution has been used but our experience now indicates that it is less effective than oral administration of the drug. The

advantages of obtaining a high local concentration of sulfadiazine in the lung with a low blood concentration justifies its trial in some patients with chronic infection

PROGRAM FOR REPEATED BRONCHIAL RELAXATION

Since helium-oxygen therapy is not generally available, two regimens will be outlined, the first without helium therapy and the second including its use

1. **Without Helium-Oxygen Therapy**—The aim of treatment in both intractable asthma and status asthmaticus is to produce as complete relaxation of the bronchi as possible by the cumulative effect of several procedures. The effect of repeated relaxation is to usher in a state of remission of the symptoms of severe asthma. In patients who are seriously ill with continuous dyspnea and cyanosis, oxygen therapy¹ is indicated to prevent the consequences of untreated anoxia, especially respiratory failure. In other cases in which repeated injections of adrenalin accomplish temporary and transient relief, oxygen therapy may not be required. Intractable asthma may then be treated either in the home or hospital, or in office practice, utilizing the methods which follow

(a) Rectal instillation of 0.5, 0.6 or 0.7 gm of aminophylline in 20 cc of water is carried out. This procedure is then repeated morning and night for approximately five days, and then continued once at night for three weeks to three months, depending on the severity of the disease. In some patients, aminophylline by rectum is given three times daily.

(b) Inhalation of a spray of 1 per cent epinephrine or vaponefrin is given after the rectal instillation of aminophylline and at four- to eight-hour intervals when wheezing respiration recurs. A hypodermic injection of 0.5 to 1.0 cc of a 1:1000 solution of adrenalin may rarely be necessary at the start of the program but the sooner it is discontinued the better. The epinephrine solution may be nebulized either by means of the handbulb or by an oxygen stream from a cylinder. If an oxygen cylinder is available, 0.5 cc of the drug is nebulized at a flow of 4.5 liters per minute. At the same time, 0.5 cc of 1 per cent neosynephrin is also nebulized. The open end of the nebulizer should be inserted well into the mouth above the tongue with the lips open.

(c) The saturated solution of potassium iodide is administered, 1 cc three times daily for the first week and then 0.3 cc morning and night for an indefinite period. When acne breaks out the drug is stopped until it disappears and then begun again at a dosage of 0.5 cc once daily.*

* In some patients with bronchial asthma, excessive formation of mucus may result from prolonged administration of potassium iodide. In these cases the drug should be stopped, since difficulty may be experienced in eliminating too abundant secretions from the bronchi.

(d) Dilaudid is given, preferably by mouth, $\frac{1}{20}$ grain, once daily for four or five days and then discontinued. For acute severe paroxysms of asthma, hypodermic administration, $\frac{1}{32}$ grain, may be used at the outset but it is far preferable to utilize this drug either by mouth or dissolved in the aminophylline solution. At times, it is serviceable to give dilaudid by mouth twice a day, $\frac{1}{20}$ grain, for a period not longer than five days. When dilaudid is discontinued codeine may be prescribed for one to two weeks, 0.03 to 0.06 gm. twice daily.

(e) Intravenous injection of 50 cc. of 50 per cent glucose may be employed if the above program does not manifestly result in marked improvement by the third day. It may be repeated on two following days or on alternate days for two additional times.

(f) If the patient appears to show little improvement as the result of instillation of rectal aminophylline, an intravenous injection in the middle of the day of 0.48 gm. may be given. In some cases the patient may be refractory even to aminophylline. This is more apt to take place in those cases that have had repeated frequent subcutaneous injection of adrenalin.

(g) Rectal instillation of 50 to 90 cc. of ether with an equal amount of olive oil may be given, in patients refractory to this program.

(b) Sedation is generally best obtained with phenobarbital, 0.1 gm. two or three times daily. Seconal or amytal may also be used at night.

2. With Helium Oxygen Therapy.—The above program is used, when helium-oxygen therapy is available, by the addition of the administration of 25 per cent oxygen and 75 per cent helium in a hood under 3 to 6 cm. water positive pressure, two hours twice daily. If the Meter mask is available, in the hospital or at home, the patient is treated with inhalation of an 80 per cent helium 20 per cent oxygen mixture for one hour two or three times daily. In office practice, helium therapy is given for one hour following a rectal injection of aminophylline. In cases which manifest cyanosis, a flow of 1 to 2 liters of oxygen is added to a helium-oxygen flow of 6 to 8 liters per minute. The inspiratory valve is removed in administration of helium-oxygen therapy by mask. Our practice has been to terminate administration of helium after a five-day period but to continue rectal instillation of aminophylline for a period of three weeks to three months, as mentioned above.

In many cases aminophylline by mouth may be advantageously employed on arising in a dosage of 0.2 or 0.3 gm., to prevent wheezing during the day. When rectal administration of the drug is discontinued, oral medication may be substituted, for a prolonged period. Since aminophylline is mentally stimulating the evening dose may cause the patient to be wakeful. If actual insomnia is induced seconal, 0.1 to 0.2 gm., may be required. For patients who still have some residual asthma after a program of bronchial relaxation, aminophylline 0.2 gm., is prescribed after breakfast and on retiring for an indefinite period. Inhala-

tion of the nebulized spray of epinephrine (or vaponefrin) for mild wheezing and coughing, especially on arising, is frequently necessary in chronic cases of bronchial asthma with considerable expectoration. Hypodermic injection of adrenalin is almost always stopped completely.

COMMENT AND SUMMARY

The disturbance in the physiology of breathing produced by constriction in the bronchial passageway is the basis for the treatment suggested in this paper. In a number of patients with intractable asthma, specific desensitization therapy has been found ineffective to prevent recurring attacks of bronchial spasm, which is often accompanied by varying degrees of functional pulmonary emphysema. Palliative treatment with adrenalin is of little value, affording temporary or transient relief in the majority of patients. Furthermore, repeated frequent injection of adrenalin is apt to result in a disease manifesting itself by increasingly severe attacks of bronchial spasm.

The principle of repeated bronchial relaxation is not considered as a palliative remedy, since it may usher in a freedom from the symptoms of the disease for periods as long as one to three years. In the majority of cases treated in the manner described, the symptoms of severe asthma have been either absent or mild for approximately seven months. Although recurrence of more severe asthma will take place in many patients, the simplicity of the program is such that the patient may again become free from the condition in its severe and, at times, invalidizing form. In a small percentage of patients, no lasting remission is obtained and attempts to relax bronchial spasm must be maintained. In this group, rest and sedation are required for a prolonged period.

Although the results of repeated relaxation of the bronchiolar circular muscle were first observed as a consequence of helium-oxygen therapy, the use of this principle in the management of patients with severe asthma may now produce similar results in those clinics in which expert provision of helium-oxygen inhalations is not available. The cumulative and summation effect of procedures which result in relaxation of the spastically contracted bronchial muscle is the central theme of this principle of treatment. None of the measures advocated will produce the type of lasting remission which is the aim of this treatment, if administered for a short time only. Intravenous injection of aminophylline is the single, most effective remedy now available for the initial treatment of intractable asthma or status asthmaticus. However, to stop treatment with one or two or three injections of aminophylline because the patient is no longer in a state of severe asthma is to allow the disease to become progressively more severe as time goes on. To rely on injections of adrenalin to take care of recurrent

asthma is to invite subsequent serious disability in most patients with bronchial asthma. Our experience indicates that the more frequent adrenalin injections become, the more likely is the patient to develop a state of refractoriness to adrenalin and, therefore, of severe asthma. Adrenalin in any form provides a transient release of bronchial spasm, but it should not be considered as a measure which promotes progressive bronchial relaxation.

Repeated use of aminophylline does result in progressive bronchial relaxation in most patients with severe asthma. It is true that a certain number of patients will become refractory to aminophylline. Under these circumstances, inhalation of helium-oxygen mixtures, or rectal instillation of anesthetic doses of ether, or one of the procedures outlined in this paper, may be employed. Since intravenous injection of aminophylline twice a day for a week and once a day for a series of three weeks to three months is impractical, the rectal instillation of adequate dosages of aminophylline has been resorted to. Fortunately, this route of administration when used carefully will result in a relief of the symptoms of asthma comparable to that achieved by intravenous injection. Furthermore, the rectal employment of the drug is far less apt to create the dizziness and other manifestations of circulatory disturbance which intravenous treatment at times produces.

The complete program of bronchial relaxation includes, in addition to aminophylline, all other measures which result in bronchial relaxation. A new conditioned reflex may be set up in the patient in which his response to the environment in which he lives is different than it was previously, despite the existence of allergic factors over which the patient has no control. Physiologically directed therapy may, therefore, be appraised as a specific remedy for treatment of intractable asthma, although it is admitted at the outset that a final cure of the disease is neither aimed at nor expected. This principle of treatment however, makes it possible for many patients who otherwise endure more or less chronic and severe asthma to be free from the severe manifestations of the disease for the greater part of the time.

Variable degrees of constriction in the bronchial passageway occur in chronic pulmonary disease. This narrowing of the lumen of the bronchi may be caused by inflammatory swelling or by bronchial spasm. In either event the principles of treatment described for bronchial asthma are frequently applicable to conditions such as bronchiectasis, pulmonary fibrosis and emphysema, chronic bronchitis and bronchiolitis. Increasing the diameter of the smaller bronchi aids, not only in the relief of dyspnea and in preventing the consequences of increased negative pressures on the pulmonary epithelium but also in facilitating drainage of retained secretions. In some instances this physiological approach towards the treatment of chronic pulmonary disease is of considerably more value than attempts to rid the patient

of old foci of infection which may have originally acted as causative factors in the condition

The intelligent use of oxygen treatment in patients with chronic pulmonary disease, in whom dyspnea and cough are the predominant features, may be of very considerable value in retarding the course of the disease and in providing increased comfort

It should be emphasized that the allergic factor should be investigated in all patients with bronchial asthma and the measures developed in the noteworthy advances in allergy should be employed whenever they are applicable, the use of physiologically directed therapy in bronchial asthma is offered as an *additional* helpful procedure to combat persisting or recurrent bronchial spasm in intractable cases

OBSTRUCTIVE PULMONARY EMPHYSEMA

JULIUS L WILSON, M D , F A C P *

AND

THOMAS FINDLEY, M D , F A C P †

EMPHYSEMA is a disease characterized pathologically by distention and inelasticity of the lungs and clinically by reduced vital capacity and dyspnea Viewed as an immediate threat to life it is not particularly important, but it is a serious and common cause of prolonged distress It seems appropriate to include an account of it in a symposium on chronic diseases

The brilliant studies of Laennec¹ published in 1819 form the cornerstone of our knowledge of pulmonary emphysema, and his theories regarding the etiology and pathogenesis are still accepted in essence Rokitsky² was the first pathologist to describe the microscopic changes by modern technic, Brown-Séguard³ pioneered in its experimental production, and Sir William Jenner's⁴ studies were enormously fruitful Indeed, it may be said that little of a fundamental nature has been added since

PATHOGENESIS

Laennec was the first to appreciate the importance of bronchial obstruction in the production of chronic pulmonary distention Pointing to the common occurrence of bronchial catarrh, he postulated that air drawn into the lung during inspiration became partially trapped In 1845 Mendelssohn⁵ and in 1857 Jenner⁴ independently emphasized the importance of forced expiration in the production of alveolar distention It is conceivable that violent expiratory efforts such as occur during cough may distend peripheral and unsupported alveoli, but prolonged muscular expiration can only compress the greater bulk of lung tissue

There is agreement then regarding the importance of respiratory obstruction Disagreement lies in whether pulmonary distention occurs during inspiration or expiration, but the weight of evidence appears to support Laennec's contention that it occurs chiefly during the inspiratory phase Inspiration is always an active process, whereas expiration

From the Section on Internal Medicine, Ochsner Clinic, and the Department of Medicine, Tulane University School of Medicine, New Orleans

* Associate Professor of Medicine, Tulane University School of Medicine, Visiting Physician, Charity Hospital in New Orleans, Associate in Internal Medicine, Ochsner Clinic

† Assistant Professor of Clinical Medicine, Tulane University School of Medicine, Director of Section on Internal Medicine, Ochsner Clinic, and Visiting Physician, Touro Infirmary

is a passive act dependent largely upon the elastic recoil of the lung tissue. If the bronchial passages are continuously narrowed, as in chronic bronchitis, or intermittently constricted as in bronchial asthma, it seems reasonable to expect that air will be drawn more readily into the lungs than expelled.

Various investigators have attempted to produce pulmonary emphysema in laboratory animals. Acute pulmonary distention has been observed to follow stimulation of the vagus nerves or drug-induced constriction of bronchial musculature. Chronic and irreversible enlargement and rupture of alveoli have been produced by techniques which obstruct the flow of air through the trachea, and similar changes have followed the exposure of animals to low barometric pressure for prolonged periods of time. The common denominator for all of these experiments is, of course, increased respiratory effort. Paine⁶ has reviewed the literature on emphysema in animals and added observations of his own.

Quantitative evidence supporting the thesis of Laennec has been found by those who have measured intrapleural pressure under various circumstances. Normally, intrapleural pressure is subatmospheric during both respiratory phases. It should become more negative whenever greater inspiratory activity is required to move air through narrowed bronchial tubes, and this diminished pressure must inevitably lead to pulmonary distention and to an increase in residual air. Brill, Prinzmetal and Brunn⁷ demonstrated experimentally that drug-induced bronchospasm resulted in diminished intrapleural pressure, and later Prinzmetal⁸ confirmed this finding in clinical asthma. Others⁹ demonstrated increased residual air during asthmatic paroxysms. Very much earlier Brown-Séquard had observed alveolar distention to occur after electrical stimulation of the vagal nuclei in dogs, and Kountz and Alexander¹⁰ made direct measurements of a similar nature.

The thorax must, of course, adapt itself to the progressive enlargement of the lungs. Since soft tissue gives way more readily than bony structure, the diaphragm becomes depressed and ultimately fixed in the inspiratory position. This is one of the most reliable signs of obstructive emphysema, and is a matter of great physiological import because the excursion of the diaphragm accounts for approximately 40 per cent of normal vital capacity. As the diaphragm becomes more and more useless, the accessory muscles of respiration grow in importance. The abdominal muscles attempt to compensate for the loss of diaphragmatic function but their effect is usually negligible, and the burden of respiration falls on the intercostal and accessory muscles. In time, therefore, the thorax becomes relatively fixed in an inspiratory position and the typical barrel-shaped chest achieved. Whenever the diaphragm can descend no more and the chest wall expand no further intrapleural pressure then becomes positive and remains so throughout

the respiratory cycle. A positive intrapleural pressure imposes an added burden not only upon the respiratory act but upon the circulatory system as well, and sets up a train of events which will be referred to later.

The forces which make expiration possible are complex and need not be described here in detail. It is sufficient to state that pulmonary elasticity is an extremely important factor, since expiration is normally a passive process. Once the ability of the lung to resume its former volume is lost, emphysema becomes irreversible. Infection, prolonged distention and perhaps an inherent tissue weakness all contribute to the loss of elasticity of the lung, which is such a central feature of the disease. Christie¹¹ showed by simultaneous measurements of tidal air and intrapleural pressure that the normal lung is an almost perfect elastic body and that this ability to recoil is greatly diminished or altogether lost in advanced emphysema. Intrapleural pressures approaching atmospheric indicate that pulmonary distention is irreversible.

It should be stated that other theories concerning the pathogenesis of emphysema exist but none of them has received appreciable experimental or clinical support. Freund¹² believed that the thorax became fixed in its characteristic inspiratory position because of primary ossification of the costal cartilages, and he devised a surgical treatment which later proved unsuccessful. Loschke¹³ showed how kyphosis of the thoracic spine may enlarge the thoracic cage in the anteroposterior diameter and maintained that pulmonary distention was secondary to this mechanical distortion. Kountz and Alexander¹⁰ and Kerr and Lagen¹⁴ have shown how a "postural" or nonobstructive type of emphysema may result from skeletal deformities and have performed a great clinical service in separating the two types. Suggestions that emphysema is the result of primary atrophy of elastic tissue, of nutritional changes in the alveolar walls, and of hereditary defects have not gained support.

PATHOLOGY

The essential pathologic change consists in enlargement and coalescence of terminal alveoli. The septa between adjacent alveoli become so perforated and the remnants so atrophied that large air sacs are formed, a process which considerably diminishes the surface area of the available respiratory endothelium. Evidence of interstitial inflammation is often seen microscopically. Early in the disease the capillary beds may be unaffected but progressive distention leads to obliteration of blood supply and to lymph stasis as well.

Grossly, the lungs are pale and irregularly pigmented. They fail to collapse when the thorax is opened and may be voluminous enough to fill the supraclavicular spaces, cover the precordium and anterior mediastinum and depress the diaphragm. They feel dry and bloodless, Laennec likened them to a pillow of down. There may be subpleural

bullae and blebs of various sizes, the rupture of which may result in spontaneous pneumothorax. Atheroma of the pulmonary artery is common

Lung Volume and Its Subdivisions

Fig. 38—Effect of obstructive pulmonary emphysema upon the components of the total lung volume

RESPIRATORY CHANGES IN CHRONIC OBSTRUCTIVE EMPHYSEMA

As a consequence of the loss of pulmonary elasticity it is impossible for the patient to empty the lungs as fully as a normal person. The

residual air of the lungs is thus greatly increased, whereas normally it is around 1000 cc after the deepest possible expiration, in well developed emphysema the residual air may be as much as 3000 or 3500 cc. The tidal air is somewhat increased to compensate for the diminished respiratory surface of the lung. The complementary air is greatly decreased by the fact that the chest is already in full inspiratory position, and the supplemental air is only moderately decreased. The vital capacity is thus decreased anywhere from 20 to 60 per cent, principally by a diminished volume of complementary air (Fig 38).

Expiration, which is normally passive, becomes active. In addition to the internal intercostal muscles, all the accessory muscles of expiration are called into play. The diaphragm, no longer pulled up by the elastic

Fig 39—Depression and immobility of the diaphragm in emphysema. *Left*, full inspiration, *right*, full expiration. The horizontal lines mark the eleventh rib posteriorly.

recoil of the lungs, assumes a low position and hence loses much of its efficiency as a muscle of inspiration. Its contraction in this position may actually narrow the lower part of the chest and its motion may be paradoxical. The abdominal muscles are frequently relaxed in the patients with pulmonary emphysema, and consequently fail to support the abdominal viscera and to raise the diaphragm on expiration (Fig 39).

Incomplete mixing of gases in extremely emphysematous lungs produces an interesting distortion of acid-base balance. Since alveolar carbon dioxide tension is high, plasma bicarbonate rises and the plasma chloride falls. These changes superficially resemble those seen in certain types of alkalosis, but they are really due to excessive carbonic

acid. It is doubtful whether this mild acidosis contributes much to the clinical picture.

There is no entirely satisfactory explanation for this retention of carbonic acid and for the anoxemia which commonly accompanies advanced cases. The latter is, of course, responsible for the cyanosis and the polycythemia so frequently seen in this disease.

CIRCULATORY CHANGES IN PULMONARY EMPHYSEMA

The intrathoracic pressure is negative as a result of the elasticity of the lungs and the difference between the size of the thorax and the size of the lungs at rest. This negative pressure in the potential pleural space, acting on the mediastinum, contributes materially to the return of the blood to the heart by the great veins. Moreover, its fluctuation from -6 cm. of water to -3 cm. of water pumps the blood into the vessels and into the auricles of the heart. With the loss of elasticity which characterizes pulmonary emphysema, the intrathoracic negative pressure approaches atmospheric. It varies from -1 to -2 cm. of water on inspiration and 0 to $+2$ cm. of water on expiration. Blood returning to the heart is, therefore, drawn into the thorax by a much less negative pressure on inspiration and may actually be held back by the positive pressure on expiration. The amplitude of the change in pressures between inspiration and expiration also being reduced, the pumping action is much feebler.

The effect upon the lesser circulation is similar. Both blood and lymph in the lungs themselves are not moved along by as great a change in intrathoracic pressures. In a normal person the pumping action of the changing intrathoracic pressures contributes little to the resting circulation of blood through the lungs. Under conditions of violent exertion with physiological dyspnea, the contribution of rapidly and widely changing intrathoracic pressures to pulmonary circulation is much greater. Both at rest and on exertion the flow of lymph from the lungs is chiefly dependent upon the changing intrathoracic pressures. The decreased amplitude of the respiratory fluctuations and pressures in emphysema would tend to allow lymph stasis in the lungs. However the shift toward atmospheric, or above atmospheric, level may actually squeeze the lymph out of the lungs on expiration. Clinically it is noteworthy that pulmonary edema is not a complication of pulmonary emphysema as long as the cardiac function is adequate.

PHYSICAL SIGNS

The diagnosis of pulmonary emphysema is one which may be made by careful inspection alone. The *form of the thorax* and the *mode of breathing* are the chief physical signs. With the overexpansion of the lungs the thorax tends to approach a roughly spherical shape—maxi-

Expiration 36 inches

Inspiration 37½ inches

Fig 40—Patient with obstructive pulmonary emphysema showing shape of thorax and its fixation in the inspiratory position Note use of accessory muscles of respiration

Fig 41—Far advanced pulmonary emphysema Note the depressed diaphragm, the radiolucence of the lung fields, the bullae at the right apex and the dropped heart.

nal volume for a closed space with fixed surface area. This results in the "barrel-shaped" chest with increased dorsal kyphosis, anteriorly arched sternum, short neck, horizontal ribs and wide subcostal angle. In this position of deep inspiration the respiratory excursion of the ribs is diminished, and the thorax seems to move more or less as a whole. The accessory muscles of respiration are called into play, both on inspiration and on expiration, with the slightest exertion (Fig. 40). Expiration is considerably prolonged and active. Frequent additional findings on inspection are cyanosis of the lips and nail beds, and some degree of clubbing of the fingers.

The other physical signs are corroborative. On percussion there is a uniform hyperresonance over both lungs extending over the normal area of cardiac dullness and almost to the bottom of the costophrenic sulcus. The deep liver dullness is obliterated. The breath sounds are diminished in intensity, with the expiratory phase prolonged but not changed in pitch. The heart sounds are distant. Roentgenograms of the chest show an abnormally clear lung in contrast with the hilar markings (Fig. 41).

DIFFERENTIAL DIAGNOSIS

There are relatively few conditions which offer any difficulty in differentiation from obstructive emphysema. Overdistention of the lungs from *severe physical exertion*, *high altitude* or *bronchial asthma* may temporarily simulate emphysema. The circumstances under which the distention occurs are sufficient, as a rule, to indicate the cause. The periodicity and typical form of asthmatic attacks plus the history distinguish bronchial asthma from obstructive emphysema.

It must be emphasized that inspection of the thoracic cage alone may lead to errors in the diagnosis of chronic obstructive emphysema if not checked by functional study of the lung. In patients of the hypersthenic body type the thorax may appear to be barrel-shaped. When such persons are middle aged, or past middle age, and when they are obese, this appearance is often striking. These patients are often dyspneic when erect and have no shortness of breath when lying down. On further examination, it is found that in the absence of true emphysema the chest expansion is good, expiration is passive, the percussion note is not unduly hyperresonant, the breath sounds are normal, the diaphragm is high and the vital capacity is not materially reduced. This is the picture of *postural emphysema* described by Kerr and Lagen.¹⁴

Thoracic deformity due to increased *kyphosis of the dorsal spine* may also simulate pulmonary emphysema and possibly may in time produce some degree of emphysema as the lung loses its useful elasticity. As in postural emphysema associated with body build and obesity already described, the function of the lung is not seriously impaired, at least at first. Chest expansion is good, percussion note is not hyperresonant, the breath sounds are normal, the diaphragm descends

freely and the vital capacity is only slightly reduced. Cyanosis and clubbing of the fingers are not observed in either of these conditions.

The differential diagnosis of *cardiac decompensation* may give more trouble, particularly in the person with a large and deep thorax. Dyspnea, orthopnea and cyanosis are found in both emphysema and cardiac failure. Dependent edema and enlargement and tenderness of the liver are not seen in emphysema unless there is also an added element of right sided heart failure. However, there may be some degree of left sided failure without these signs. The venous pressure may be increased in emphysema as in cardiac failure, but seldom to a pronounced degree. The vital capacity is reduced in both conditions. In the absence of definite evidence of cardiac enlargement or physical signs of cardiac disease, the electrocardiogram and the circulation time must be depended upon to furnish the critical evidence as to whether pulmonary emphysema or some degree of cardiac decompensation is responsible for the patient's symptoms.

It should be borne in mind that in actual practice the line between postural emphysema and obstructive emphysema on the one hand and between obstructive emphysema and cardiac failure on the other is not always sharply drawn. The patient with postural emphysema at the age of forty may have obstructive emphysema at fifty-five as a result of repeated infection and a loss of pulmonary elasticity. In patients with obstructive emphysema of long standing, cardiac decompensation eventually develops. Therefore, transition phases and combinations of emphysema and cardiac decompensation are seen as frequently as the simple types of these conditions.

PREVENTION AND TREATMENT

Prevention—The fundamental cause of emphysema, namely, the gradual loss of pulmonary elasticity, cannot be prevented. The contributory causes which produce bronchiolar obstruction should be combated in so far as possible. Bronchospasm due to asthma should be treated and the young asthmatic patient should be protected from recurrent attacks by desensitization or by removal from the environment in which asthma occurs. Recurrent and persistent bronchial infection should be treated by attacking the cause, if possible. Infected nasal accessory sinuses, infected tonsils and infected gums often are responsible for chronic bronchial infection and can be treated. Chronic irritation of the bronchial mucosa by dust, smoke and smoking may contribute to the prolongation of bronchitis. Such irritants should be avoided entirely or minimized by protective measures. When acute bronchitis occurs, it should be treated energetically and thoroughly until cured.

Treatment—The treatment of obstructive emphysema is largely the amelioration of an irreversible condition.

DRUGS—Drugs are often useful in relaxing bronchospasm and in thinning or decreasing the bronchial secretion. *Ephedrine sulfate* is a valuable remedy which gives considerable relief to some patients. The action of epinephrine is too transitory to do any lasting good. In a recent case of obstructive emphysema without asthma the vital capacity rose from 1500 cc. to 2300 cc. within ten minutes after the subcutaneous administration of 1 mg. of epinephrine. Similar but less dramatic results may be obtained by the continuous administration of ephedrine. *Atropine* both dilates the bronchi and diminishes the bronchial secretion. It should be given in sufficient dosage to produce definite clinical effects.

The *expectorants* are helpful in cases in which the secretions are thick and tenacious. Inhalations of 5 to 10 per cent carbon dioxide and oxygen for a few minutes three to four times a day furnish probably the most effective method of loosening and clearing the secretion. Unfortunately, this treatment is seldom available outside of the hospital. Potassium iodide in full doses, syrup of iodic acid or ammonium chloride in sufficient dosage may be used. The following prescription may be found useful.

R

Ephedrine sulfate	10
Tincture of belladonna	30.0
Potassium iodide	36.0
Syrup of cherry	120.0
Water to make	240.0

Label Teaspoonful every 4 hours.

MECHANICAL AIDS—Since the malfunction in pulmonary emphysema is largely a difficulty in expiration due to the loss of pulmonary elasticity, a large number of methods have been suggested for overcoming this difficulty. *Exercises* have been suggested to improve the expiration. These generally consist of forcible expiration aided by pressure of the hands on the lower ribs. Unfortunately, the exercises are only of temporary benefit and the difficulty is continuous, few patients will persist in such exercises.

Belts to support the abdomen and hence to elevate the diaphragm have been devised by Kountz and Alexander¹⁰ and Kerr and Lagen.¹¹ A great many of the sufferers from obstructive emphysema are relieved by these belts. It is difficult to determine in advance which patient will obtain relief from such support of the diaphragm. Such a belt must support the whole abdomen and actually raise the diaphragm so that in its more normal position it may function effectively on inspiration. The belt must be elastic to a certain extent to allow the abdominal wall to expand as the diaphragm descends. By trying manual support of the

abdomen or by applying an elastic bandage around the abdomen and observing the effect under the fluoroscope, one may obtain some idea as to whether a belt of this type will be beneficial

Inhalations of oxygen and helium mixtures will, of course, temporarily relieve the difficulty in respiration. However, it is obvious that such measures can be applied only in exceptional cases

SURGICAL TREATMENT—Operative treatment has been attempted in the past on the basis of various theories of the production of emphysema. It has not been successful. Mobilization of the costal cartilages or other measures to change the mobility of the thoracic cage cannot overcome the fundamental difficulty in the loss of elasticity in the lungs

CLIMATIC TREATMENT—Many of the patients with obstructive emphysema can lead useful lives and maintain a general level of health until a superimposed respiratory infection increases the obstruction and leads to true disability. This is most apt to occur during the colder months. Also, the patient subject to bronchial asthma may be unable to escape the antigen causing the bronchial spasm in his normal environment. The change of climate, preferably to one that is warm and dry, may thus be the most important therapeutic agent in prolonging the life and usefulness of these types of patients. The southern half of Florida, southern California, or certain parts of the southwest may offer a haven to such patients. Health resorts with an altitude much above sea level may, on the other hand, lead to serious anoxemia in patients who have a high degree of obstructive pulmonary emphysema

TREATMENT OF THE CHRONIC ANEMIAS

PAUL REZNIKOFF, M D *

GENERAL REMARKS

IN recent years such great advances have been made in the study of the causes and treatment of the anemias that this field has become a *scientific* part of clinical medicine. Nevertheless, the therapy encountered in daily practice frequently demonstrates little if any appreciation of the fundamental contributions to the subject. Many patients are given "shotgun" remedies so that no knowledge of a possible effective drug can be determined. This may eradicate all clues when it becomes necessary to diagnose the cause of the condition. Such procedures also are costly, time-consuming and inefficient. Indeed, it is not uncommon to encounter patients who have been treated for "anemia" because they have complained of fatigue or similar symptoms, in whom no blood study has been made to show the existence of any deficiency. In fact, few patients are investigated adequately to determine the cause of their anemia. There is no excuse for such a state of affairs, because in most cases the examinations are simple and can be performed in any physician's office. While it is obvious that some patients have obscure blood dyscrasias, the etiology of which defies even the most careful investigation, most anemias can be diagnosed and of these many can be treated successfully.

Why Patients with Anemia Are Often Poorly Treated—Some of the reasons patients with a decrease in red blood cells and hemoglobin are poorly treated are

1 It is not always realized that anemia is merely a sign of many diseases, and its treatment without an understanding of its cause is no more logical than treating fever without determining its etiology. *Anemia is never primary, always secondary*

2 Many physicians seize upon anemia as something tangible to treat rather than go through the time-consuming and laborious procedure of eliciting a complete history and performing an adequate physical examination which in the long run will probably save time and may result in the eradication of the cause of the condition. If the depression of erythrocytes and hemoglobin is only moderate, it is probable that the patient's symptoms and signs are not due to the anemia per se but are

From the New York Hospital and the Department of Medicine, Cornell University Medical College, New York City

* Associate Professor of Clinical Medicine, Cornell University Medical College, Attending Physician, New York Hospital, Visiting Physician, Bellevue Hospital

due to the same underlying disease which is producing the red blood cell and hemoglobin decrease as one of its effects

3 Some practitioners feel that "shotgun" remedies will do no harm and may cure the complaints and they will thus save themselves considerable trouble.

4 The simple basic laboratory examinations necessary to classify an anemia are not generally known, nor are the early evidences of response to therapy clearly appreciated.

Basic Procedures in Diagnostic Survey—Before discussing therapy it is desirable to enumerate the general procedure to follow in studying a patient and it is also necessary to have some simple classification of the main causes of anemia. The basic examinations are the following

- 1 A complete history paying special attention to familial diseases, bleeding dietary abnormalities, contact with toxic substances, drug administration, soreness of the tongue, paresthesias, gastro-intestinal symptoms, and jaundice.
- 2 An adequate physical examination including eyeground studies, and pelvic and rectal examinations
- 3 Urine examination.
- 4 Red blood cell count hemoglobin determination by an acceptable method, white blood cell and differential counts.

If possible it is desirable to have

- 1 An hematocrit determination.
- 2 Reticulocyte counts before treatment is instituted and at proper times after therapy is begun.
- 3 Stool examination for occult blood and for parasites and ova.
- 4 Gastric analysis with histamine stimulation and perhaps x ray studies of the gastro-intestinal tract.

In some cases it may be necessary to have a hypotonic saline test (fragility test) performed and a bone marrow study

CLASSIFICATION

In order to treat erythrocyte and hemoglobin deficiency intelligently, it is essential to know the cause or the type of the defect. Anemias may be classified etiologically or according to cell size and hemoglobin content.

In itemizing the various causes of anemia, acute hemorrhage is usually not listed since the blood will return to normal in a previously healthy individual due to adequate stores of iron and other substances necessary for red blood cell and hemoglobin production

Classification Based on Etiology—A simple classification of reduction of red blood cells and hemoglobin based on etiology is the following

I Deficient Bone Marrow Function

A Faulty bone marrow nutrition

1 Iron deficiency

(a) Chronic blood loss

(b) Defective iron ingestion or absorption

(c) Pregnancy

- 2 Extrinsic or intrinsic factor deficiency
- 3 Protein deficiency
- 4 Thyroid substance deficiency
- 5 Copper and other heavy metal deficiency
- B Depression of bone marrow
 - 1 Toxic (nephritis)
 - 2 Chemical (benzol, gold salts, sulfonamides, arsphenamine)
 - 3 Physical (x-ray and radium)
 - 4 Chronic infections
 - 5 Mechanical (leukemia, Hodgkin's disease, neoplasms)
 - 6 Refractory or aplastic anemia
- II Hemolytic Anemias
 - A Intrinsic
 - 1 Hemolytic, spherocytic jaundice
 - 2 Sickle cell anemia
 - 3 Paroxysmal, nocturnal hemoglobinuria
 - 4 Hemolysis due to isoagglutinins and isohemolysins
 - 5 March hemoglobinuria
 - B Extrinsic
 - 1 Malaria
 - 2 Hemolytic streptococcus or staphylococcus infections
 - 3 Sulfonamides
 - 4 Lead
 - 5 Favism
 - 6 Sensitization to Rh factor

Morphologic Classification—A morphologic classification based upon cell size or volume and relative hemoglobin content may be of considerable aid to the physician in diagnosing the type of anemia. In order to determine these factors it is necessary to have a red blood cell count, a hematocrit reading and a hemoglobin value. From these factors, volume index or mean corpuscular volume and color index can be calculated. On the basis of these findings, a classification can be made according to cell volume and relative hemoglobin content. While all combinations may be possible, as a rule the following morphologic types are found:

- 1 Normocytic, normochromic anemias (due to renal disease, many cases of aplastic anemia, and following infection)
- 2 Microcytic, hypochromic anemias
 - (a) Iron deficiency
 - (b) Mediterranean anemia
- 3 Macrocytic, hyperchromic anemias
 - (a) Pernicious anemia
 - (b) Sprue
 - (c) Carcinoma of the pylorus
 - (d) Cirrhosis
 - (e) Acute leukemia
 - (f) Aplastic anemia
 - (g) Bothriocephalus latus infestation
 - (h) Pregnancy
 - (i) Gastro-intestinal lesions such as fistulas

THERAPY

With the above-mentioned facts in mind we are now prepared to consider the treatment of the various types of anemia, which will be discussed in the order of the etiologic classification presented previously.

Iron Deficiency Anemias—It is most important to remember that iron therapy is of value only for patients suffering from iron deficiency and in no other anemia. Since there are only three causes of iron deficiency—chronic blood loss, faulty iron intake and loss of iron to the fetus by a pregnant mother—the administration of iron in any other condition is not indicated. When one considers the almost universal habit of prescribing iron to all anemic patients regardless of the cause, the absurdity of such practice is obvious. Moreover, Balfour and his co-workers¹ have shown that the absorption of iron depends upon only one factor and that is the depletion of the body storehouses of iron. No matter how low the hemoglobin may be, iron therapy can be of no help unless there is a deficiency of iron in the supply depots of the organism.

It is important in the treatment of iron deficiency to determine the cause for such a defect. If the patient is bleeding, every effort must be made to stop such blood loss. This is relatively simple in cases of bleeding hemorrhoids or in patients who bleed from fibroid tumors. It is not as easy to treat a bleeding peptic ulcer and much more difficult to prevent bleeding from esophageal varices secondary to cirrhosis of the liver. But in all cases an attempt must be made to learn the cause of iron deficiency. In "idiopathic," hypochromic, microcytic anemia of women, especially after menopause, no apparent blood loss may be found but the anemia may have begun in early years during periods of menorrhagia or in previous pregnancies.

Faulty iron ingestion usually produces anemia in growing children or in girls who are losing blood during menstruation. In such cases the problem is one of iron balance as shown by Heath.² Where no blood loss is present or no excessive demand for iron is found as in growth or pregnancy, faulty iron ingestion does not cause iron deficiency. For example, malnourished elderly men who have no blood loss and even show evidences of pellagra or scurvy rarely have any appreciable anemia, and certainly no signs of lack of iron.

The classical picture of depletion of iron is hypochromia, microcytosis, low color index and low volume index or mean corpuscular volume. In some cases of long standing anemia of this type a normocytic picture may be found but this is not usual. In addition to pallor, dyspnea on exertion, rapid pulse rate, slight fever, dependent edema and low blood pressure, it is not unusual to find brittle fingernails, sore mouth, especially at the angles, dysphagia, dry hair, and in some cases a palpable spleen.

If the diagnosis of iron deficiency is established and the cause of the condition is corrected, if possible, the treatment is specific and simple—namely, the administration of iron in adequate dosage, over a proper time interval and under clinical and hematological control. Many types of iron have been used and in most cases have been successful. However, the object of iron therapy is to give the patient a cheap, effective and nonirritating remedy. Most therapists have found that ferrous salts are more easily tolerated by patients than ferric salts or reduced iron. For the average adult patient, *ferrous sulfate* has been proved to be an efficacious remedy. This may be prescribed in capsule or tablet form. For example, an effective prescription is ferrous sulfate, exsiccated USP, 0.2 gm (3 grains) containing about 60 mg of iron. In order to eliminate irritation of the stomach, the medication should be given immediately after meals. To further minimize possible gastro-intestinal distress, it is a good policy to start with one capsule or tablet following each meal and increase the dose daily and gradually by one capsule or tablet a day (not per dose) until the patient is receiving three capsules or tablets after each meal. This would provide an intake of somewhat more than 0.5 gm of iron a day, which should be ample for most patients. If it is found that such a dosage causes gastro-intestinal disturbances, such as epigastric discomfort, nausea, diarrhea or constipation, the dose can be reduced and maintained at the predistressing levels.

More easily tolerated than the solid ferrous sulfate is the drug in liquid form and this is especially true in individuals who have difficulty in swallowing tablets or capsules and in children. A good prescription is *elixir of ferrous sulfate*, 4 cc, three times a day after meals. This elixir contains 0.1 gm ($1\frac{1}{2}$ grains) of ferrous sulfate in each 4 cc or 38 mg of iron. In adults it is desirable to increase the dosage 4 cc a day until the patient is receiving 12 cc three times a day after meals, or almost 350 mg of iron a day. Since most patients must take iron medication for long periods—not less than a month and in some cases indefinitely—the total quantity ordered should be adequate, 300 capsules or tablets and 500 to 1000 cc of the elixir at a time.

A few patients may be intolerant to ferrous sulfate. It has been found that many of these individuals can take *ferrous gluconate* in fairly adequate amounts,³ as 0.3 gm (5 grains). Each tablet contains 36 mg of iron. The dosage is started at one tablet after each meal and increased gradually until the patient is receiving nine tablets a day, unless gastro-intestinal symptoms occur. While such dosage affords only 325 mg of iron a day, it is probable that this is adequate in most cases. In some patients it has been found that good response is obtained with as little as three tablets or slightly more than 100 mg of iron a day.

Some clinicians still use many of the older iron remedies and if these cause no untoward effects, there is no objection to them. One of these

is 50 per cent aqueous solution of ferric and ammonium citrate, 4 cc, taken through a tube or straw with meals to avoid staining the teeth. This affords 6 gm ($1\frac{1}{2}$ drams) of the iron compound a day or 1 gm (15 grains) of iron. Another of the older remedies is *ferrous carbonate* (Blaud's mass), 0.3 gm (5 grains), four capsules three times a day after meals, which gives 380 mg of iron a day. The capsules are preferable to the pills and the medication should be freshly made to prevent oxidation to the ferric state which would result in poor absorption.

Many patients suffering from iron deficiency anemia are found to be achlorhydric or hypochlorhydric. Some of these individuals fail to respond adequately to iron and in these cases it is desirable to give with meals *dilute hydrochloric acid*, U.S.P., 2 to 4 cc. diluted with half a glass of fruit juice or water to which sugar is added. The liquid is sipped through a tube or straw to protect the teeth. If a patient must have his meals outside of his home, capsules of acidulin may be given with meals, each capsule being equivalent to 0.6 cc (10 minims) of hydrochloric acid or glutamic acid hydrochloride—0.325 gm equivalent to the same quantity of acid.

In pregnancy some obstetricians believe it advantageous to prevent iron deficiency anemia by giving the mother iron therapy as a prophylactic, 300 mg of iron a day being considered adequate. All physicians do not consider such therapy necessary or even desirable and believe that when the pregnant woman has had an adequate diet she will not develop iron deficiency. Moreover, it must be remembered that a moderate reduction in red blood cell count and hemoglobin in the latter months of pregnancy is due to blood dilution rather than to anemia and is considered physiological by many workers.

The effect of iron therapy depends in the last analysis upon the response of the patient. If a reticulocyte peak is obtained within five to ten days after therapy is started, it is certain that the hemoglobin level will reach normal with continued treatment. The height of the reticulocyte peak will be inversely proportional to the initial hemoglobin level. A normal blood count should be attained in three to four weeks after the onset of treatment. Thereafter maintenance therapy should be continued and red blood cell counts and hemoglobin determinations may be made once a month. Some patients will require no further treatment after the blood has attained a normal level especially if the cause of the iron deficiency has been eradicated. But in many individuals, especially those with 'idiopathic' hypochromic anemia and in cases of achlorhydria, iron therapy must be continued always to prevent a return of the anemia.

One important fact should be emphasized in a consideration of iron therapy. *Iron should be given by mouth and not by parenteral injection.* Not only are iron compounds toxic when injected but the amounts which can be given parenterally are of very little value. Many

physicians have been misled by reports which have reference to experimental work mainly in animals. If a patient cannot tolerate iron by mouth, it is quite certain that the injection of iron would be highly undesirable and valueless.

Foods which contain a high percentage of iron should be used especially when the anemia is due to faulty ingestion of iron. These are liver, kidney, meat, tripe, eggs, apricots, peaches, prunes, raisins, spinach, beet greens and whole grain cereals.

Most textbooks urge physicians to use certain *general measures* such as adequate physical and mental rest, fresh air, sunshine, massage and hydrotherapy. These are all desirable in any patient but cannot take the place of specific therapy. In the absence of these commendable hygienic measures, patients will recover from iron deficiency anemia with adequate iron therapy and the elimination of the cause of the defect.

While there is experimental evidence that such factors as Whipple's liver factor, chlorophyll and bile salts may aid in hemoglobin formation, there is no indication that any patient failed to respond to iron therapy because of the lack of these agents.

Pernicious and Other Macrocytic Anemias—*Liver extract* is a specific remedy for deficiency of intrinsic factor which is the cause of pernicious anemia. It is also effective in other macrocytic anemias such as the anemia of sprue, "tropical" nutritional macrocytic anemia, the anemia of *Diphyllobothrium latum* infestation, macrocytic anemia of pregnancy and the macrocytic anemias associated with hypothyroidism and some intestinal lesions such as gastrocolic fistula. It may also be of value in idiopathic steatorrhea or celiac disease. Macrocytic anemia found in carcinoma of the pyloric portion of the stomach may show some response when liver extract is given but obviously does nothing to cure the disease and sometimes such improvement prevents the diagnosis if x-ray studies of the stomach are not made. In cirrhosis of the liver, macrocytic anemia is not infrequently seen and liver extract sometimes produces an increase in red blood cell count. This, however, is not usually striking. Many of the above mentioned conditions may be due to deficiency in extrinsic factor, but even in such states liver extract has been found to be effective. Patients, suffering from malnutrition, especially of those foods which contain the extrinsic factor, may respond not only to liver extract but to a diet rich in meat or to large amounts of brewers' yeast.

Unless a patient has macrocytic anemia or one entirely or in part due to lack of intrinsic or extrinsic factor, there is no justification for the use of liver extract. Moreover, if there is no reticulocyte response in five to ten days and a conspicuous red blood cell rise within two or three weeks after onset of therapy, the continuance of liver therapy is not indicated. In many of the macrocytic conditions, liver therapy is only one factor in the treatment of the disease. For example in idio-

pathic steatorrhea, careful attention to diet, consisting of low fat, high protein, low starch, high simple carbohydrate and high vitamin intake is essential. Frequently, pancreatic therapy and measures to control diarrhea are necessary. It is impossible to review the complete therapy of all diseases in which macrocytic anemia occurs, but it must again be emphasized that the entire patient should be treated and not only his blood.

In order to simplify the problem of the use of liver extract, it might be well to describe its administration in an uncomplicated case of relapse in pernicious anemia. Since liver extract is not destroyed or excreted it is desirable to give more rather than less of the material. While the average patient may need only 1 U.S.P. unit a day, there is no method of standardizing the material except by the patient's response. Patients differ markedly in the amount of liver extract required.⁴ One other fact needs emphasis and that is that intramuscular injection is the route of choice for administration. Only in the rare patient who is sensitive to parenteral treatment should oral therapy be considered. There is no good evidence that any one type of liver extract is superior to any other if the product has been accepted by the United States Pharmacopoeia. This statement holds true for both refined and crude extract.

The average patient should receive 15 to 30 units of an acceptable liver extract intramuscularly daily until the reticulocyte peak is reached that is, for one week to ten days. After this period the frequency of injection may be decreased to three times a week until the red blood cell count reaches 4,000,000. Then the periods of therapy and the amount will depend upon the patient's response. For example some individuals maintain a normal count on 15 units a month. A few may need 15 units a week. Other factors influence the patient's maintenance dose such as infections, neurological signs and symptoms and possibly arteriosclerosis. Certainly a patient who has paresthesias, a diminished vibratory sense and other neurological involvement should receive more therapy than a subject free from these. These patients should also take large amounts of vitamin B for their peripheral neuritis.

The following table gives some indication of the *expected reticulocyte response* at its peak if therapy is effective. The peak varies inversely with the initial red blood cell count before therapy is begun.

Initial Red Blood Cell Count	Average Percentage Increase of Reticulocytes	Minimum Percentage Increase of Reticulocytes
500,000	60	50
1,000,000	35	30
1,500,000	25	18
2,000,000	15	12
2,500,000	10	7
3,000,000	4	4

The question whether *hydrochloric acid* should be given in pernicious anemia cannot be answered in the same way in all cases. Most patients do not need hydrochloric acid, but in general individuals who complain of gastric distress or diarrhea and have no other reason to explain these symptoms do well when they take acid. This should be administered as outlined previously in the paragraph dealing with iron deficiency.

It is rarely necessary to give *iron* in pernicious anemia. Some authors feel that if the hemoglobin rise does not keep pace with the improvement in red blood cell count, iron therapy is indicated. However, if the patient does not have a real iron deficiency, it is not necessary to add another medication. In other words, true anemia rather than a relatively low hemoglobin value should determine the need for iron therapy. The patient rather than the blood count should be treated.

Anemias Due to Other Nutritional Factors.—One of the essential substances necessary for the proper production of hemoglobin and red blood cells is protein. Whipple⁵ has demonstrated its importance. Anemia due to *protein* deficiency has been seen clinically in cases of marked malnutrition when the protein intake is especially low. Usually patients also suffer from multiple deficiencies when they are especially deficient in protein ingestion. If an individual has an adequate and well rounded diet, the protein is usually sufficient. However, in nephrotic conditions, where the urinary loss of protein is marked, it must be increased above the usual normal requirements.

While *copper* and *other heavy metals* are essential for the proper formation of hemoglobin, these elements are necessary in such minute amounts that they are amply provided by the ordinary diet or in the impurities found in medication. Therefore, there is no justification, except perhaps in infants, to add these substances. There is no evidence in ordinary practice that copper has any appreciable value when added to iron.

Much work has been published to suggest that *vitamins C and B* are advantageous in the treatment of nutritional anemias. Recently it has been shown that the anemia of scurvy is due to iron deficiency because of the concomitant low iron intake in vitamin C deficient diets and can be corrected by iron alone. As far as vitamin B is concerned, animal experiments are suggestive that some of the B factors are efficacious, but no conclusive experiments have been performed to indicate that vitamin B therapy is needed to correct human nutritional anemia.⁶ Therefore, at the present time it is not considered necessary to add any vitamin to iron or liver therapy. The many pharmaceutical products which contain vitamins should not be used unless there is also evidence of vitamin deficiency.

Anemia of Hypothyroidism—Hypothyroid patients may show anemia which may be normocytic, macrocytic or microcytic. In such indi-

viduals, it is necessary to give, in addition to thyroid extract, medication for the blood deficiency. If the subject has a macrocytic condition, parenteral liver extract should be given as in pernicious anemia. In the microcytic type, iron should be administered as in the treatment of iron deficiency. Normocytic anemia in hypothyroidism also occurs and yields to thyroid therapy rather slowly. In such cases, some workers assume that the patient is suffering from iron and intrinsic factor deficiency and give both liver and iron in addition to thyroid extract. It is not known whether the anemia responds more rapidly to such therapy than to thyroid substance alone.

Anemia of Pregnancy—While this subject has been discussed previously, it is important to consider this state as an entity. In the first place, it must be reiterated that there is dilution of blood in the latter stage of pregnancy and that this is not a true anemia and cannot be corrected by iron or liver therapy. Iron deficiency has already been discussed. Also the true macrocytic anemia of pregnancy has been mentioned and its treatment with liver extract described. There are a few patients who have multiple deficiencies and these may have hypochromia and macrocytosis. However, the anemia may be pronounced and be of a normocytic, normochromic type. In such rare cases, it may be justifiable to give iron and liver. The frequent practice of administering iron and liver to all pregnant patients with even mild anemia is not a good procedure.

Multiple Deficiency Anemia—In severe malnutrition and in some iron deficient pernicious anemia patients, it has been found necessary to give an optimum diet and adjuvant iron and liver therapy. It is important to try to determine the predominant deficiency first and administer the indicated remedy. If a reticulocyte response can be followed for each hematinic, treatment can be undertaken more intelligently and, in the long run, economically, both with respect to finances and time.

Duration of Therapy—Pernicious anemia patients will have to be treated for the duration of their lives. They should be so instructed. The same may be true of many iron deficient individuals especially those suffering from "idiopathic" hypochromic anemia. Pernicious anemia of pregnancy usually disappears with the termination of pregnancy. Hypothyroid subjects whose anemia is corrected may need no further treatment for their blood if the thyroid status is maintained at a normal level.

Depression of the Bone Marrow—In most cases in which bone marrow depression occurs, therapy can be successful only if the depressing agent is removed or the causative factor is corrected. This is obviously not possible in *chronic nephritis*. In general the anemia runs parallel to nitrogen retention. Loss of blood due to long-continued and persistent hematuria even of microscopic amounts or frank bleeding from other parts of the body which occurs in uremia may contribute to the

anemia The only palliative treatment is transfusions, which should be given for symptoms and signs of anoxia.

The same therapy should be used in cases of *aplastic* or *refractory anemia* There is no evidence that iron, liver or any other therapy except transfusions is of help in this condition The purpose of transfusions should be to keep the patient comfortable and free from such disabilities as dyspnea and extreme weakness and not to correct the blood picture Transfusions probably do not stimulate the depressed bone marrow In determining the frequency of transfusions, the patient's economic status, activity, family obligations, and the realization that we are dealing with an incurable disease should all be considered by the physician Some individuals carry on quite well for years with transfusions of 500 cc on a few successive days every month, or few months Other patients need transfusions at much more frequent intervals Each case must be studied individually to determine a plan of treatment

Certain *chemical depressants*, such as sulfonamides and arsphenamine, may have only a temporary effect This may also be true of benzol and gold salts In other patients any of these chemicals may produce an irreversible condition and result in a true aplastic state of the bone marrow, and transfusions will be necessary to maintain life If the reticulocyte count is above normal it usually means that the bone marrow is functioning well and will recover eventually The same principle may be true for physical agents such as x-ray and radium

When the bone marrow is depressed because of chronic infections, therapy must be designed to cure the infection and improve the anemia by palliative transfusions

Leukemia, Hodgkin's disease and metastatic lesions in the bone marrow produce anemia by crowding out the erythrogenic tissue If irradiation therapy is successful, the blood will often show improvement It must be remembered, however, that irradiation itself may cause some bone marrow depression and should be administered with constant check of the blood count Often transfusions are necessary as a supportive measure until irradiation becomes effective

Hemolytic Anemias —OF INTRINSIC ORIGIN —The treatment depends upon the cause of hemolysis The most satisfactory hemolytic condition to treat as far as cure is concerned is *hemolytic spherocytic jaundice* of the familial type Splenectomy is specific therapy Although there is no change in the abnormality of the red blood cells, removal of the spleen will end hemolysis in almost all cases There is one feature of this condition which merits mention In preparing the patient for operation, transfusions may be necessary to raise the blood count However, these patients tend to hemolyze readily the donor's blood as well as their own and suffer transfusion reactions without obtaining optimum benefit from the transfusions Consequently, it is best to save

the transfusions for the operative and postoperative period if the blood count permits this procedure. Most individuals will stand an operation well if the red blood cell count is about 3,500,000 with a comparable hemoglobin value.

Certain of the hemolytic states do not yield to any therapeutic measure. *Sickle cell anemia* can be treated only symptomatically. There is no good evidence that splenectomy is of value. Transfusions may be necessary but these often given severe reactions. *Paroxysmal nocturnal hemoglobinuria* and *hemolysis due to isoagglutinins* and *isohemolysis* do not yield to therapy.

March hemoglobinuria is due to excessive physical activity or long-continued strain due to posture. Often this condition corrects itself and is not as a rule of a serious nature.

OF EXTRINSIC ORIGIN.—Hemolytic anemia due to extrinsic agents can be corrected, if not of an overwhelming nature, by treating the offending factor. This is true of *malaria* and *hemolytic bacterial infections*. Anemia due to *lead poisoning*, especially of the acute type, usually responds to the proper treatment of plumbism and with improvement, the blood returns to normal in time.

When the *sulfonamides* cause hemolysis, the decrease in blood count usually occurs soon after the drug is given. If the defect is moderate and the reticulocyte count is above normal, the patient usually recovers without any special treatment. If the anemia is severe, the drug may have to be stopped and transfusions given.

Favism is due to an anaphylactic reaction to the inhalation of pollen or eating the raw fava bean after previous sensitization. This type of hemolysis may prove fatal. It is prevalent in Italy, but only a few cases have been reported in this country. Prevention is, of course, the best type of therapy. During an acute attack, transfusions must be given.

Recently much light has been thrown on the cause of hemolytic anemia following transfusions to postpartum patients. It has been found that usually the donor frequently the husband has an Rh factor in the blood which is not present in the wife. She becomes sensitized to the Rh factor by the fetus who has inherited the positive Rh factor from the father. The recipient has thus developed an Rh antibody which in contact with the Rh antigen produces a marked reaction resulting in hemolysis. To avoid such a condition which may be fatal it is important to test the mother's blood for the presence or absence of an Rh factor. If the blood is Rh negative she must only be given blood from an Rh negative donor. It is also possible that repeated transfusions given from Rh positive donors to a negative recipient may eventually produce anti Rh antibodies in the litter and lead to severe hemolysis.

Many other hemolytic anemias have been described such as Lederer's acute hemolytic anemia and paroxysmal (cold) hemoglobinuria presumably due to syphilis. For these rare conditions the reader is referred to textbooks of hematology.[†]

Transfusions—It is beyond the scope of this paper to give a detailed account of the indications for transfusion or the methods of matching or administering blood. Since this is an important procedure in the treatment of many anemias, it should be pointed out that in most cases transfusions are only *palliative*. The purpose of transfusions is to tide a patient over until the cause of an anemia can be eradicated and the disease becomes self-limited. Transfusions are invaluable in correcting anoxia or preparing an individual for operation or irradiation, but the transfused blood does not become a permanent addition to the patient's circulation. It is therefore important to appreciate the transitory nature of the donor's blood and to emphasize the fact that anemias can be cured only when a person's bone marrow can manufacture red blood cells and hemoglobin normally.

CONCLUSIONS

Anemia is only a sign of disease and its treatment depends upon an understanding of its cause and correlation of this depression of red blood cells and hemoglobin with the entire clinical picture. To treat anemia with "shotgun" therapy is usually uneconomical and often results in failure. Iron should be given only in iron deficiency states; liver therapy, in macrocytic anemias, and transfusions, to treat anoxia and as a palliative measure. Before therapy is started an adequate study should be made to determine the cause and type of the anemia so that logical treatment may be undertaken. Lack of therapeutic success may be due to the hopelessness of the patient's illness, but sometimes it is due to the failure of the physician to understand the nature of the condition and to appreciate the fact that all anemias are *secondary* to some pathological state in the patient. The patient rather than a blood picture must be treated.

CARE OF THE PATIENT WITH CHRONIC HEART DISEASE

EUGENE A. STEAD, JR., M.D.* AND JAMES V. WARREN, M.D.†

THE treatment of congestive heart failure has gradually improved as the basic physiology of heart failure has become better understood. In order to understand the principles underlying therapy, let us trace the natural history of a patient with congestive heart failure.

As long as the heart is able to put out the blood required for the daily routine of the patient, heart failure does not occur. When the heart is not able to pump the amount of blood necessary to maintain the circulation at a normal level during the patient's daily routine, symptoms of heart failure develop. If, at this time, the patient is put at rest, the symptoms of heart failure will quickly disappear without medication. The heart is still capable of maintaining a normal circulation at rest. Only during activity is the heart inadequate. Studies of the cardiac output in the patient at this time will show that the resting cardiac output is within normal limits. Thus, the patient can be compensated for a time by reducing his activity and reducing the amount of blood pumped per twenty-four-hour period.

In time, regardless of limitation of activity, the cardiac output becomes inadequate and the symptoms of heart failure again develop. By the proper use of digitalis, the physician can strengthen the heart and cause it to pump blood more effectively. Again the symptoms of congestive failure disappear. After a time the cardiac output again decreases and in spite of digitalis and limitation of activity the symptoms of congestive failure reappear. The resting cardiac output will now be low and salt and water retention will occur even at rest. Because many of the symptoms of congestive failure result from the interference in function of the lungs and other organs due to excessive retention of salt and water, the patient can be kept comfortable even with a moderate decrease in cardiac output if such retention of salt and water is kept at a minimum. This can be done by the use of diuretics and by limiting the dietary intake of sodium. In time salt and water retention occurs in spite of constant therapy, and the patient becomes waterlogged and dies.

In summary, then, we can help the patient with congestive failure in three ways: (1) by rest so that the body requirements for blood are

From the Medical Service of the Grady Hospital and the Department of Medicine, Emory University School of Medicine, Atlanta, Georgia.

less and the daily output of the heart can be decreased without interfering with body economy, (2) by strengthening the failing heart with digitalis so that it can maintain an output compatible with the necessary activity of the patient, and (3) by eliminating the salt and water which tend to be retained when the cardiac output becomes insufficient to support the patient's daily routine of living. In the above discussion, for the sake of clarity, we used each of three measures separately. In practice we combine them.

REST

The load on the heart can be eased in two ways: (1) by limiting the patient's physical activity and (2) by correcting any abnormal condition which causes the resting cardiac output to be elevated. Physical activity can be decreased by weight reduction if the patient is obese. He is instructed to be slow and deliberate in his movements, to walk slowly rather than briskly, to avoid stairs and inclines. He is given appropriate rest periods in the day and goes to bed at an early hour. If the patient is orthopneic, a cardiac bed is desirable. Sedatives should be used as necessary to insure restful nights. If the patient becomes more decompensated because of an acute infection, morphine by mouth at bedtime may be necessary to insure sleep. Certain diseases cause the resting cardiac output to be elevated, and a greater than normal amount of blood must be pumped to maintain the health of the patient. Congestive failure may be present in these patients at rest, even though the cardiac output is greater than it would be in normal subjects under similar conditions. Thyrotoxicosis, anemia, nutritional deficiency, arteriovenous aneurysm and patent ductus arteriosus all put strain on the heart even at rest. If such a condition is present, its correction may enable the heart to compensate and greatly improve the patient's prognosis.

DIGITALIS THERAPY

That the administration of digitalis increases the ability of the failing heart to perform its work is generally accepted. This action of digitalis on the myocardium can be counted on both in patients with regular rhythm and in those with auricular fibrillation. Indeed, digitalis is beneficial in patients with myocardial failure even in the presence of complete heart block. The increased number of digitalis products now available presents a confusing array to the physician. There is little evidence, however, that any one preparation has a more beneficial effect on the myocardium or fewer toxic effects than any other. Therefore the choice of drug depends upon such factors as the rapidity of digitalization desired, the preferred method of administration, expense, and the doctor's experience with a given drug.

If rapid digitalization is not necessary, the old reliable powdered digitalis is still most widely used. Since this is a natural product, and

therefore variable, some method of biological assay is required. That amount of digitalis found to be equal in activity to one unit of the standard is labeled 0.1 gm. digitalis. In each of the last three editions of the United States Pharmacopoeia the standardization of digitalis has been modified. This has caused considerable confusion. In some localities U.S.P. X digitalis is still available. The reference standard for this digitalis was relatively weak and the method of comparison was the frog assay. Because the digitalis unit U.S.P. X happened to be approximately equal to the Hatcher-Brody cat unit, an independent unit not related to U.S.P. standards, physicians became accustomed to using the terms interchangeably. With the advent of U.S.P. XI, the reference standard was so increased in potency that one U.S.P. XI unit of digitalis was almost 50 per cent stronger than a U.S.P. X unit and hence no longer equal to the Hatcher-Brody cat unit. Finally, the latest edition, U.S.P. XII, standardizes digitalis against a new standard and by a different method (a cat method, but not that of Hatcher and Brody). The newest product appears to be midway in potency between that of U.S.P. X and XI. Thus, there are available at the present time three digitalis products varying so considerably in strength per unit that the difference in potency is clinically detectable. The physician should be aware of this difference in potency and know which product his patients are receiving. As the newer pure digitalis products become more available, much of the difficulty may be circumvented.

The individual requirement of digitalis for complete digitalization is quite variable, making a definite statement of dosage almost impossible. It has become apparent that much of this variation is due to differing efficacy of absorption of the drug from the gastro intestinal tract. In general about 1.5 gm. (U.S.P. XII) are required. The speed of administration depends upon the condition of the patient. As the point where digitalization can be expected is approached the doses should not be large, and before each is administered the patient should be questioned about early symptoms of toxicity. Particularly important is the loss of appetite which is often the earliest such symptom.

A physician should be familiar with at least one of the drugs available for rapid *parenteral* digitalization. In this clinic lanatocid C, a pure glycoside from digitalis lanata, has been used and proved very satisfactory.¹ The usually accepted digitalizing dose of 1.6 mg., given either intravenously or intramuscularly, and most often in two equal doses, produces good clinical response with a low incidence of toxic effect. It is possible that the apparent lack of toxicity is due to the fact that this dose is slightly less than a complete digitalizing dose. Soon after the lanatocid C has been given digitalis leaf is started by mouth in doses of 0.1 gm. three times a day and continued at that dose until the patient has a satisfactory clinical response or shows evidence of toxicity.

PREVENTION AND TREATMENT OF EDEMA

Measures for preventing the accumulation of salt and water are of primary importance in treating congestive failure. Whenever the degree of activity of the patient is increased beyond the capacity of the heart to pump blood, salt and water accumulate. In the early stages of congestive failure, this occurs during activity. Thus the patient develops edema while carrying on his usual activities. If, by rest, the degree of activity of the patient is decreased to where the heart is capable of maintaining a normal circulation, the edema subsides as the kidneys excrete the accumulated salt and water. In time, as the circulation becomes inadequate at rest, edema forms while the patient is in bed unless special measures are taken to prevent it.

The retention of the sodium ion appears to be the primary cause of edema in cardiac failure.² The exact mechanism by which this occurs has not been determined. The retention of chloride and water is apparently secondary to the retention of the sodium ion. Edema in congestive failure can be minimized in two ways: (1) by limiting the intake of sodium and (2) by increasing the excretion of sodium. The observation that retention of sodium is necessary for the formation of edema is of great importance, since it eliminates the need for decreasing the water intake in patients with congestive failure, provided their sodium intake is very low. Water does not accumulate in the patient with congestive failure unless that water can be made isotonic with body fluids by the addition of sodium chloride.³ If the necessary sodium is not present, the water is rapidly excreted in the urine. It must be remembered that the sodium is present in the ash of most foods and that sodium retention with edema formation is possible even though the salt intake is limited unless acid-ash foods are selected. Schemm⁴ has published diets which yield an acid-ash and contain not more than 0.5 gm of salt. If this diet is followed strictly fluids may be given freely. Many patients will not eat a low salt, acid-ash diet. If the patient is undernourished, it may be better to increase the salt intake so that the patient will take more food, and then to increase salt elimination through the kidneys by the use of diuretics.

Diuresis.—Patients who are no longer able to maintain an adequate cardiac output by rest or by the use of digitalis must receive diuretics at regular intervals. It is now recognized that dyspnea caused by heart failure is an indication for diuresis, though there is no demonstrable peripheral edema and though the venous pressure is normal. In many patients with left ventricular failure, edema accumulates in the lungs before it is demonstrable elsewhere. Attacks of paroxysmal nocturnal dyspnea may be prevented by regular use of diuretics. The diuretic selected and the frequency of its administration depend on the rapidity with which fluid accumulates. If the patient has chronic congestive failure and the heart has not compensated on rest and digitalis, the

physician must plan a long-range program of active treatment for the rest of the patient's life. The patient can usually be prevented from developing massive edema until his terminal illness. The most common mistake is to give the diuretic at too infrequent intervals.

The *xanthine diuretics* are useful because they can be given by mouth, but have the disadvantage of being much less powerful than the mercurial diuretics. There are many preparations available, the dosage varying somewhat with the particular product.

Mercupurin and salyrgan with theophylline are the *mercurial diuretics* in common use. The original dose should not exceed 0.5 to 1 cc. After the initial injection they are usually given intravenously in doses of 1 to 2 cc. at intervals of two days to two weeks, depending on the tendency of the patient to retain salt and water. These substances cause marked irritation when given subcutaneously and care must be taken to be certain that the needle is cleanly in the vein before the injection is carried out. If no veins are found it may be injected into the muscles of the buttocks. The mercurial diuretic is usually administered in the morning so that the resulting polyuria will not interfere with the patient's sleep. Many patients complain of weakness after marked diuresis. In rare instances toxic reactions may occur. If an injection of 1 to 2 cc. produces marked weakness, it is better to give smaller doses at more frequent intervals.

If the mercurial diuretic is ineffective, it may be supplemented by the administration of *ammonium chloride*. This is given in enteric-coated capsules in doses of 6 to 8 gm. daily for two to three days. At the end of that time the mercurial diuretic is given and the ammonium chloride discontinued. This routine is repeated as often as necessary to keep the patient free of dyspnea and edema.

Urea in doses of 90 gm. per day is an effective diuretic. It has the disadvantage of an unpleasant taste, but if the patient tolerates it, urea has the great advantage of being taken by mouth. It can be used alone or in combination with ammonium chloride and a mercurial diuretic. In the advanced stage of congested failure when the patient is a complete invalid, it may be necessary to give urea daily, mercupurin or salyrgan with theophylline in 2-cc. doses every second or third day and ammonium chloride in doses of 6 to 9 gm. for two to three days at five day intervals. These measures are combined with the low sodium acid ash diet.

Other Measures to Control Edema—In certain patients fluid tends to accumulate in the chest in spite of good cardiac care. The removal of this fluid by *thoracentesis* will allow the patient to breathe much more comfortably. At times one is surprised by the great improvement in dyspnea which results from the removal of a relatively small amount of fluid. Five hundred cubic centimeters of fluid in the chest of a person with normal lungs will not cause dyspnea. Five hundred cubic

centimeters of fluid in the pleural cavity of a patient whose vital capacity is greatly diminished because of edematous lungs from heart failure may cause marked dyspnea.

Certain patients with chronic mild failure complain of the fact that they have to void after a few hours in bed and that once they are awakened they cannot go back to sleep. These patients accumulate edema in the lower part of the body during the day because of the high hydrostatic venous pressure in the portion of the body below the heart. On going to bed, this fluid enters the circulation and is excreted by the kidneys so that after a few hours the patient has to void. If the patient lies down for a couple of hours after dinner, before going to bed, a portion of the excess fluid will be voided and the patient may not be awakened to void.

As the patient becomes more inactive, the edema in the lower extremities may be aggravated by the immobility. The lower extremities remain motionless for long periods of time. The venous pressure in them is high because of the hydrostatic pressure of the column of blood in the veins, and because of the lack of motion the lymphatic flow is very slow. This edema can be reduced by the use of *elastic bandages* applied before the patient rises and removed after he returns to bed. Some patients with advanced congestive failure are more comfortable in a chair than in a bed. A patient should not be forced to lie in bed if he prefers to sit up. Indeed, there may be danger in placing him in bed. The edema which has accumulated in the lower extremities remains there while he is in the chair. If placed in bed, the venous pressure in the lower extremities will be lowered and the fluid may enter the blood stream and be deposited in the lungs.

Any infection in the body may precipitate acute cardiac decompensation. Respiratory infections in particular are dangerous. The patient should have complete bed rest if he develops a cold, sore throat, or bronchitis. In patients with chronic heart disease, exacerbations of congestive failure are usually secondary to infection rather than to unusual exertion. If cough is troublesome it must be controlled by the administration of codein.

Acute Pulmonary Edema—As a result of infection, overwork, ingestion of large amounts of sodium chloride, omission of digitalis, too long intervals between the administration of diuretics, or because of progressive myocardial disease, sudden dramatic episodes of pulmonary edema frequently occur during the course of chronic heart disease. This can happen during the day, but it is particularly prone to occur during sleep. The patient awakens with marked dyspnea and orthopnea. He is frightened and apprehensive. The extremities are cold and the patient sweats profusely. The heart rate is fast, the arterial pressure is frequently elevated. The lungs are usually filled with moist râles and the patient may raise bloody, frothy sputum. In other patients bron-

chial spasm occurs, and the patient presents the clinical picture of asthma. In some patients the lungs are clear on auscultation because the edema is interstitial rather than in the smaller divisions of the bronchial tree. On examination by x-ray the lungs show signs of congestion.

Treatment consists of emergency measures to control the acute episode, and attempts to prevent further recurrences. Morphine sulfate in a dose of 15 mg. is given hypodermically to quiet the patient. If the peripheral veins are not already distended and if the extremities are not already tight with edema, blood can be shunted from the lungs to the extremities by the use of tourniquets. Rubber tubing can be used but blood pressure cuffs are preferable. The tourniquets are applied to the proximal portions of the extremities as close to the trunk as possible. They are inflated to a pressure midway between the systolic and diastolic arterial pressures and are left in place till the acute attack has subsided. Then they are removed one at a time so that the blood accumulated by the tourniquets is not restored to the general circulation too abruptly. If the veins are already distended because of a high venous pressure or if the subcutaneous tissues are tight with edema, tourniquets cause little pooling of blood in the extremities. Under these circumstances the rapid removal of 500 to 1000 cc. of blood by venesection may produce great improvement in the patient's condition. The administration of a high concentration of oxygen by the use of a Boothby mask or an oxygen tent may be helpful. If the patient has not been digitalized, rapid digitalization by the intramuscular or intravenous routes may be indicated. Recurrences are prevented by proper use of digitalis, rest, dietary restriction of sodium chloride and the persistent use of diuretics.

In the discussion of the treatment of the specific symptoms of cardiac failure we must not lose sight of the fact that we are treating a patient as well as a disease. The patient will be anxious about his own welfare and he will interpret any physiological disturbances in function as evidence of progressive heart disease. The counsel of an intelligent physician will aid greatly in giving him mental as well as physical rest.

CONGENITAL PATENT DUCTUS ARTERIOSUS. AN EVALUATION OF ITS SURGICAL TREATMENT

GEORGE E BURCH, M D , F A C P *

SINCE the early description of the ductus arteriosus by Galen,¹ there has been, until several years ago, relatively little change in the management of patients with a persistence of the ductus. Treatment was entirely medical, emphasis being placed on restriction of activity and the subsequent management of congestive heart failure and bacterial endarteritis as major complications. A great advance in the treatment of this condition occurred in 1938 when Graybiel, Strieder and Boyer² reported the first attempt to ligate a patent ductus arteriosus despite the fact that the patient died. This attempt at least gave impetus to further trials at ligation. As early as 1907 Munro³ developed an operative approach for ligation of a patent ductus and presented clinical evidence to prove the rational basis for such an operation, but his suggestion was ignored for thirty-one years. Success was finally achieved in 1939, when Gross and Hubbard⁴ reported the first ligation of a patent ductus arteriosus followed by recovery.

Because of the striking benefit obtained by Gross and Hubbard and the impressive results following operation in the hands of others, there has developed a wave of enthusiastic interest in the surgical treatment of patent ductus arteriosus. This can be readily understood, since the development of a safe operative procedure to correct a persistent ductus arteriosus has made it possible to convert an irreversible type of heart disease into a reversible or curable one. These rapid developments have prompted an analysis of the surgical results to date in order to evaluate better the indications and contraindications for operation.

PHYSIOLOGICAL CONSIDERATIONS

Eppinger, Burwell and Gross^{5, 6} and Eppinger and Burwell⁷ studied the circulation of the blood through the patent ductus arteriosus in man at operation and also in dogs. In these latter investigations a fistulous connection was made between the aorta and the pulmonary artery. The blood was observed to flow from the aorta to the pulmonary artery, as would be expected on the basis of the pressures in the two circulatory systems. Rarely was there any flow of blood in the

* Associate Professor of Internal Medicine, Tulane University School of Medicine, Visiting Physician, Charity Hospital in New Orleans and Touro Infirmary, Consultant in Cardiovascular Diseases, Ochsner Clinic.

reverse direction, that is, from the pulmonary artery to the aorta. This explains the absence of cyanosis. In their patients, from 4 to 19 liters of blood per minute was found to enter directly from the aorta into the pulmonary artery. This represented from 45 to 75 per cent of all the blood leaving the left ventricle.

The blood entering the pulmonary artery returns to the left ventricle via the lungs without reaching the peripheral circulation. In order to compensate for the loss of blood in the periphery, the volume output from the left ventricle must increase. This occurs without much change in that of the right ventricle. The result is a considerable increase in the work of the left ventricle, left ventricular enlargement, strain and eventual failure. There is some increase in the work of the right ventricle, as it must circulate the added amount of blood entering the pulmonary artery from the aorta. Eppinger and his associates⁵ found the left ventricle pumping four times the volume of blood expelled by the right ventricle. These effects on ventricular work explain the normal axis deviation or mild left axis deviation and the rare right axis deviation in the electrocardiogram. The patent ductus arteriosus is associated with many of the hemodynamic and other cardiophysiologic manifestations so well known in aortic regurgitation and arteriovenous aneurysm.

The *roentgenologic signs* observed by teleoroentgenography, fluoroscopy or roentgenokymography, easily explained on the basis of the disturbed physiologic condition already discussed are as follows:^{6,7} (1) greatly increased excursions of the left ventricle, (2) increased pulsations of the pulmonary artery, (3) overfilling or engorgement of the pulmonary conus and pulmonary vessels, (4) increased pulsations of the bronchovascular structure, particularly prominent near the hilar regions, and (5) enlargement of the left ventricle.

The changes in hemodynamics also explain the typical "machine-like" murmur and the other murmurs so commonly heard in this anomaly. The former murmur is characteristic when properly located in the region of the pulmonary valve of the chest. Further details of changes in the dynamics of the circulation can be found in the papers of Eppinger and his associates. It is well to point out at this time that when the ductus is successfully ligated the circulation dramatically returns to normal within a short time, a matter of seconds to hours.⁸

It is beyond the scope of this paper to discuss the anatomy, embryology, method of closure and other physiologic phenomena associated with patent ductus arteriosus. The papers of Franklin,¹ Boyd,² Barclay et al.,³ Noblick and Relman,¹⁰ Kennedy,¹¹ Kennedy and Clark,¹² and Jager and Wollenman¹³ in addition to the standard textbooks may be consulted by those interested in these phases of the subject.

RESULTS OF LIGATION OR EXCISION

Since the failure of Graybiel, Strieder and Boyer² in 1938 to ligate a patent ductus arteriosus with superimposed infection, there have been in the literature many reports on the surgical treatment of this anomaly. Gross and Hubbard⁴ in 1939 reported the first successful ligation. Since then these authors and others have reported many surgical results at such a rapid rate that it is difficult to determine the chronologic order of publication, especially since several authors have written several reports on the same patients within a few months' interval. In spite of these facts an attempt has been made to list in chronological order of publication from most of the available reports the results of ligation of the patent ductus arteriosus (Tabulation). By this means at least an impression of the published results can be obtained. It must be remembered that there have been many unrecorded cases, especially fatal ones, which are less apt to be reported. Therefore, such statistics will indicate only the trend of the results of surgical treatment.

ANALYSIS OF LITERATURE

In 1938 Graybiel, Strieder and Boyer² attempted to ligate a patent ductus arteriosus complicated by subacute bacterial endarteritis (*Streptococcus viridans*) but the patient died. Gross and Hubbard⁴ in 1939 reported a successful ligation in a 7½-year-old girl who showed signs of impairment in growth and cardiac enlargement. Gross¹⁴ reported his results in 4 patients one month later and at the same time described a surgical approach for the operation, three of the cases were new and the results were likewise successful.

Jones and his associates¹⁵ reported during the next month their immediate results in 7 cases. All of these patients were apparently cured or greatly benefited. One, however, died thirty days later of an infection due to the hemolytic *Staphylococcus aureus*. These authors included an addendum to this same report in which they cited 6 more successful operations making a total of 13 cases with only 1 death. Several months later they¹⁶ reported their results in 11 cases in more detail. It is a bit confusing from these articles to know which were the patients previously reported. The success of the operation is modified somewhat in the later report, since in 6 of the 11 patients a systolic murmur remained. Of course, a sufficient length of time must elapse before the results in such patients can be properly evaluated. Such overlapping of cases and variations in descriptions make an evaluation of the results in the literature difficult. Stephens,¹⁷ in the discussion of the paper of Jones and his co-workers,¹⁸ reported a death from infection on the third postoperative day. Gross, Emerson and Green¹⁸ reported a case of successful ligation of the ductus but the patient is probably one previously reported by Gross.¹⁴ Gross¹⁹ summarized his

results in 4 cases in which the ductus was ligated without a single death

Touroff and Tuchman⁹ reported a successful ligation in a 51-year-old woman with a patent ductus and superimposed endarteritis (*Streptococcus viridans*) This same patient had made a spontaneous recovery from endarteritis under medical treatment twelve and a half years before Gross,¹ summarizing his experience with ligation in 10 patients, reported 1 death from infection postoperatively, no improvement in 1 case and remarkable improvement in the remaining 8 Kerr²² in the discussion of Gross's paper²¹ cited 2 cases, a young girl who died from infection and a child who showed no improvement following ligation. In the latter case Kerr suggested the possibility of multiple cardiac lesions as the reason that complete cure was not effected by the operation

Touroff and Vesell²³ reported a cure in a 29-year-old woman who had a patent ductus arteriosus with a superimposed subacute *Streptococcus viridans* endarteritis These same writers²⁴ later reviewed their results with ligation in 4 patients with subacute *Streptococcus viridans* endarteritis superimposed upon a patent ductus arteriosus One patient, apparently the one mentioned above,²³ was cured, 2 died of hemorrhage and the other continued to show bacteremia, as the duct was too short for excision and was only ligated Gross²⁵ summarized his results again in 13 patients subjected to ligation of the ductus One died of infection, 1 was not benefited and 11 were definitely improved or cured

Gale and his co-workers²⁶ reported a successful ligation in a 19-year-old girl Miangolarra and Hull²⁷ described a successful ligation in a 20-year-old woman and a death from hemorrhage in a 12-year-old boy Castellano and co-workers²⁸ reported a case of a patent ductus arteriosus in which ligation resulted in cure Gebauer and Nichol²⁹ ligated the ductus in three patients, the 39-year-old woman died of hemorrhage but the 11- and 14-year-old children recovered and were clinically improved Bourne and his associates³⁰ ligated the ductus in a 23-year-old man with subacute bacterial endarteritis (*Streptococcus viridans* and *Haemophilus influenzae*) in whom the cultures remained positive although the patient was well sixteen months later Ligation was also performed in a 19-year-old girl with subacute bacterial endarteritis (*Streptococcus viridans*), and she was well eleven months later Sulfonamides were used in treating both of these patients Bourne³¹ again reported the same 19-year-old patient elsewhere Shapiro and Keys³² studied 23 of their patients with patent ductus and reviewed patients operated on by observers A more detailed analysis is presented by these authors in a later paper (vide infra) Cames and Gonzalez Sabathie³³ presented the case of a 10-year-old boy who made an excellent recovery following ligation of a patent ductus

Johnson and his associates³⁴ reported 7 patients in whom the ductus was ligated. One died of hemorrhage, one had subacute bacterial endarteritis (*Streptococcus viridans*) and died seven months after operation and in 5 the ligations were successful. Winn, Hughes and Sanders³⁵ ligated a ductus in a patient with subacute bacterial endarteritis (*Streptococcus viridans*) and supplemented this with sulfapyridine and heparin. One year later the patient was in excellent health. Touroff, Vesell and Chasnoff³⁶ reported their second patient with patent ductus arteriosus with subacute bacterial endarteritis (*Streptococcus viridans*) who was cured by ligation. Vedoya and his associates³⁷ described their results with ligation in 4 patients. One patient died at operation, 1 was benefited and in two the results were excellent. Nixon³⁸ reported a successful ligation in a 15-year-old girl. Touroff³⁹ reported 4 additional ligations in patients with a patent ductus with superimposed *Streptococcus viridans* endarteritis. This brought Touroff's personal series of patent ductus associated with endarteritis to 8. Since this report appeared, Touroff had had 2 additional patients suffering from patent ductus arteriosus complicated by infection who were cured by operation.

Dayton and Lindskog⁴⁰ reported a cure by ligation of another patent ductus arteriosus complicated by *Streptococcus viridans* endarteritis. Humphreys⁴¹ reported 16 ligations, all results were excellent except for a stormy convalescence in two instances. However, one year later 1 patient died of an aneurysm that developed postoperatively in the ductus and another died of bacterial endarteritis two months following operation. Dolley and Jones⁴² summarized their results again. In their series of 18 cases ranging in age from 4 to 31 years, ligation was accomplished without a single immediate operative death. One patient died several days later of a staphylococcic infection in the region of the ductus. In 4 other patients a murmur developed and in one of these a continuous murmur recurred. Keys and Shapiro⁴³ made another analysis of collected cases. These cases will be taken up in greater detail when their third and apparently most recent analysis is discussed.

Touroff⁴⁴ in his next report added 3 more cases of ligation of patent ductus arteriosus complicated by endarteritis, making a total of 11 cases, which formed the basis for his most recent report. Two patients died of hemorrhage, 6 recovered without the aid of chemotherapy, 3 continued to have positive blood cultures and 1 of these died eight months later. Harrington⁴⁵ reported a successful ligation in a patient with a superimposed subacute bacterial endarteritis (*Streptococcus viridans*), he has operated on 5 other patients with good results.

Shapiro and Keys⁴⁶ described the results of 140 ligations by 25 surgical teams, a great number of which were collected by personal correspondence with surgeons. The remainder were collected from the literature. Of these, 107 were uncomplicated and 33 were associated with a

superimposed bacterial endarteritis. Seven of the patients were from the author's series. Of the 107 uncomplicated cases, 81 were successful except for a distant short systolic murmur that remained in a few instances over the pulmonic area. In 14 the continuous murmur remained. In 6 death resulted from rupture of the duct, in 2 bacterial endarteritis developed after operation, in 1 case mediastinitis with death resulted, in 1 there was no duct to ligate (a direct anastomosis between the aorta and pulmonary artery was found so nothing was done), in 3 a vessel other than the duct was ligated (the aorta in one instance) and 2 of these died, and in 2 the diagnosis was mistaken. There was a total of 9 deaths in the 107 cases (the 2 with endarteritis after operation were not included), a mortality rate of 8.5 per cent.

Of the 33 patients operated upon in the presence of superimposed bacterial endarteritis, 20 seemed to have been completely cured clinically. Five patients died at operation of rupture of the duct and in 8 fever persisted in spite of operation. This gives an apparently favorable prognosis of more than 50 per cent in a disease with a previous mortality of almost 100 per cent. In the preceding table the reports which have been discussed are summarized in tabular form.

CLINICAL PICTURE

The clinical picture of patent ductus arteriosus may vary considerably in specific cases but in general the syndrome is fairly characteristic.^{19 21 47} The most representative feature is a loud harsh *murmur* best heard over the region of the pulmonary valve. It is usually continuous with systolic exacerbations. The loud, snappy, second pulmonic heart sound heard with the murmur produces a "machine-like" effect. The systolic murmur is crescendo and the diastolic one is decrescendo. There usually is a definite systolic thrill and often a continuous one with systolic exacerbations. The murmurs and thrills may be best elicited with the subject leaning forward and the lungs emptied to a maximum. The murmurs and thrills are produced by the blood flowing from the aorta into the pulmonary artery. These manifestations vary in degree with the size and anatomic nature of the ductus. The patients will usually give a history of the presence of a murmur from birth or since their first physical examination.

These patients usually present no cyanosis, since aerated blood is entering the pulmonary circuit from the aorta. As the patient becomes older the increased burden on the heart begins to manifest itself by *cardiac enlargement*. After a time *congestive heart failure* develops and the manifestations of left and right ventricular decompensation will gradually appear and become progressively worse. If bacterial infection of the ductus develops, then there will be a picture of *bacterial endocarditis* with the embolic phenomena present mainly in the lungs. The *Streptococcus viridans* is the most common offending organism. There

may be a wide pulse pressure with an elevated systolic pressure and even a slightly lowered diastolic pressure. This may result in peripheral vascular signs similar to those of aortic regurgitation. These patients often show definite retardation of physical and mental growth frequently to the extent of seriously jeopardizing their efficiency.

The *electrocardiogram* is not characteristic. It may vary from normal to one showing serious myocardial disease. The electrical axis may be deviated to the left or right or may not be changed from the normal. The appearance of the electrocardiogram is beyond the scope of this discussion. It is not really necessary to list the various electrocardiographic changes that might be noted.

The *roentgenographic study* is of great diagnostic significance in recognizing this anomaly.^{6, 7, 10, 21, 47} There is a definite enlargement of the pulmonary conus and the pulmonary artery and its branches. A "hilar dance" may be seen on fluoroscopic examination.⁶ The bronchovascular markings are increased. The left and right ventricles will show varying degrees of enlargement depending upon the duration of the lesion. The left ventricle shows distinct excursions with each cardiac cycle, which suggests a large stroke volume. Congestion of the lungs and other signs of congestive failure may be detected when failure is present. Infarcts in the lungs will be noted if there is bacterial endarteritis with embolism. The reader is referred to standard textbooks and monographs on cardiac disease for further details of the clinical syndrome.

LIFE EXPECTANCY AND INCIDENCE

In the presence of patent ductus arteriosus the life expectancy in untreated cases has been variously stated but in general the findings are essentially the same. Of 92 patients studied by Abbott,⁴ one-fourth died of bacterial endarteritis and an additional one-half died of slow or rapid heart failure. The average age at death in this group of 92 cases was 24 years. Gross and his associates¹⁸ estimated that a child with a patent ductus has one chance in four to live a normal length of life, one chance in four to die of bacterial endarteritis and almost two chances in four that he will die of heart failure. Bullock and his co-workers¹⁶ found in 80 cases reviewed by them that 11 (14 per cent) died as a result of the congenital lesion by the age of 14, by 30 one-half were dead, by 40, 71 per cent were dead and 2 lived to the age of 66 years. Eighteen patients (23 per cent) died of congestive heart failure, 5 (6 per cent) of rupture of the ductus, 42 (53 per cent) of bacterial endarteritis, and 4 (5 per cent) of an associated condition. Thus, 69 (86 per cent) died as a result of the lesion. In 5 the cause of death was not given and in 6 (7 per cent) death was attributed to unrelated causes. Shapiro and Keys⁴⁰ found from a review of the literature that 80 per cent of such patients eventually died of the cardiac lesion. Pa-

tients alive at 17 years of age average 35 years at death, 40 per cent dying of subacute bacterial endarteritis and most of the remainder of congestive heart failure. Wilson and Lubschez⁴⁸ found no deaths from congestive heart failure and bacterial endarteritis in 38 patients with uncomplicated patent ductus. There was one unexplained sudden death. Twenty-four were between 10 and 20 years, 12 between 20 and 30 years and 2 over 30 years of age.

The incidence of persistent ductus arteriosus varies with the series reported. Bullock and his associates¹⁰ found 133 instances of congenital heart disease in 21,000 autopsies at Los Angeles County Hospital. Thirty-six of these were cases of patent ductus, 21 of which had other associated defects. Twenty died before the age of 9 months, 10 with uncomplicated patent ductus were less than 2 months old. Every patient died as a result of this lesion. Wilson and Lubschez⁴⁸ estimated that 1 to 2 per cent of cases of organic heart disease in the adult and 5 to 12 per cent in children are the result of congenital malformations. An analysis of 54,842 reported autopsies⁷ revealed that congenital defects constituted 1.3 per cent of all cases, the reported incidences varying from 0.6 to 5.4 per cent. Of 152 patients with congenital cardiac malformations on whom autopsies were performed at the New York Nursery and Child's Hospital 10.5 per cent were cases of patent ductus arteriosus. Of the 54,842 autopsies 63 (0.11 per cent) of these patients had a patent ductus. Of the total congenital anomalies 10.3 per cent were patent ductus arteriosus. Keys and Shapiro⁴² estimated that about 20,000 persons in the United States have a patent ductus arteriosus. About two thirds of them are females.

CAUSES OF FAILURE FOLLOWING LIGATION

Gross²⁵ attributes poor results of operation to (1) failure to find the ductus, (2) a ductus too short to ligate, (3) ligation of a wrong vessel (4) hemorrhage from the ductus, (5) incomplete obliteration of the ductus (6) associated cardiovascular abnormalities, (7) wound sepsis, (8) postoperative pneumonia as well as pulmonary embolism preoperatively. The nature of these causes of failure is obvious. Most of them are technical considerations whereas some will enter into the surgical problem as they do in any major surgical procedure in the thorax. Hemorrhage is particularly apt to occur in patients with superimposed bacterial endarteritis. The infection renders the ductus friable which results in rupture or cutting through of the ligature. With improvement in the operative procedure there will undoubtedly be fewer failures.

INDICATIONS FOR OPERATION

The indications for operation are not too definite at present but certain generally accepted concepts may be enumerated.

1 The surgical risk is still not good enough in average hands to recommend operation to all patients with patent ductus arteriosus. With further improvement of the operative technic such a recommendation may be made, especially in view of the morbidity and short duration of life associated with this defect.

2 Because of the high mortality rate in those patients with superimposed endarteritis who are not subjected to ligation and the greater than 50 per cent cure (*vide supra*) following ligation, the operation should be recommended when endarteritis is present.²³ The prerequisites for successful operation are (*a*) that the vegetations be confined to the ductus and (*b*) that the ductus be of sufficient length to permit excision. (These can be determined, at present, only at the time of operation.)

3 The operation should be performed in the presence of definite cardiac decompensation, especially if it is progressing.²¹ (This would include patients who are showing signs of progressive failure, a large heart and serious disturbances in cardiac mechanism.)

4 Ligation of the ductus is indicated in patients showing definite retardation of physical and mental development.

COMMENT

It can be seen from the foregoing that the problem of patent ductus arteriosus is still unsettled. The mean mortality rate determined from the results of operations performed by many surgeons is about 8.5 per cent in cases of uninfected ductus. This does not represent the results that may be expected when a surgeon has had experience with only an occasional case or with many cases. Furthermore, as shown by Shapiro and Keys,⁴⁶ over 20 per cent of the patients operated on in 107 uncomplicated cases either died or were not benefited materially as far as the murmur was concerned.

There is no doubt that the life expectancy in persistent ductus arteriosus is considerably reduced. It is apparent too that most patients with an uncomplicated ductus are spectacularly benefited by ligation. It is also true, however, that these patients have only been followed four years after operation and only time will determine exactly what influence the operation has on the duration of life. Furthermore, in the presence of superimposed bacterial endarteritis the mortality rate for untreated cases is approximately 100 per cent, but ligation has reduced this to less than 50 per cent (*vide supra*) after a follow-up of about one year. Therefore, ligation should not only be recommended but urged if the patient has an associated endarteritis. The same is true in patients who have progressive cardiac damage and decompensation or patients with definite impairment of mental and physical development. One would nevertheless hesitate to recommend or assume the responsibilities for operation in a patient who has a patent ductus without any evi-

dence of embarrassment of health Dolley and Jones⁴² found the operation easier to perform in children 4, 5, and 6 years old If this proves to be true, then the age of the patient will influence considerably the time at which operation should be recommended

It is conceivable that in the future the operation will usually be recommended as soon as a patent ductus is discovered No such recommendation can be made at this time with the operative mortality averaging 8.5 per cent and even being greater in average hands Until the surgeons have developed a procedure that is relatively safe and the results can be predicted preoperatively with a greater degree of certainty, the operation should be reserved for those special indications already listed

SUMMARY

Most of the available case reports in the literature on ligation of patent ductus arteriosus have been reviewed The average surgical mortality was found to be 8.5 per cent in uninfected ducti The rate varies considerably, however, depending on the surgeon and his experience (Tabulation)

The operation has been recommended for all patients with the anomaly if there is a superimposed bacterial endarteritis, more than 50 per cent of such patients have been cured by ligation of the ductus It is also strongly advised for patients with progressive cardiac failure and for patients with definite impairment of physical and mental growth.

Poor results following ligation may be attributed to (1) failure to find the ductus, (2) ligation of the wrong vessel (3) wound sepsis (4) hemorrhage, (5) a ductus too short for ligation (6) postoperative pneumonia (7) associated cardiovascular abnormalities and (8) incomplete obliteration of the ductus

THE MEDICAL TREATMENT OF PEPTIC ULCER

T GRIER MILLER, M.D., F.A.C.P.*

INTRODUCTION

THE management of a patient with simple uncomplicated peptic ulcer whether gastric or duodenal is fundamentally an art rather than a science. The etiology and pathogenesis of the affection are unknown, and so its therapy must be on an empirical rather than a rational basis. In spite of that, one might expect that an analysis of the results of treatment would have led finally to the acceptance of a regimen that had proved its worth. The natural history of the disease, however, is also uncertain and in consequence one is constantly confronted with the possibility that many of the cases in any particular series would have recovered without any therapy or as a result of some associated but unrecognized factor.

Under such circumstances it is not surprising that many programs for the treatment of ulcer have been evolved that each has its advocates and that, until the disturbance responsible for its occurrence and until its pathological physiology are determined, none of the procedures can be regarded as on a truly scientific basis. In this presentation, therefore, I shall merely outline the principles of therapy which, on the basis of results from a varied and reasonably extensive experience, I personally have finally adopted in the management of the average ulcer patient and also those that I regard as most satisfactory for its common medical complications.

NATURAL TENDENCY TO HEALING

Clinical as well as autopsy data are available to indicate that many peptic ulcers heal naturally or at least without any intentional effort at treatment by either the patient or his physician. It is not uncommon for the ulcer patient to tell his doctor, on his first visit, that he has had similar symptoms previously and that in the course of weeks to months they subsided completely without any change in personal habits, environment or other routine of life and without any resort to medicinal or dietary therapy. The occurrence of gastric or duodenal perforation or hemorrhage in persons with ulcer who have had no previous symptoms, suggests that ulcerative lesions may develop and

From the Gastro-Intestinal Section (Kinsey Thomas Foundation) of Medical Clinic University of Pennsylvania Hospital, Philadelphia.

* Professor of Clinical Medicine School of Medicine, University of Pennsylvania. Chief of Gastro-Intestinal Section (Kinsey-Thomas Foundation) of Medical Clinic University of Pennsylvania Hospital.

heal spontaneously. In further support of this hypothesis, duodenal and gastric scars are often found on roentgenologic examination in subjects who at no time had had any symptoms suggestive of ulcer. Also, the fact that at autopsy, as pointed out by Sturtevant and Shapiro, gastric ulcers and gastric ulcer scars predominate over duodenal ones, whereas, clinically and on roentgenologic examination, the duodenal lesions are found in excess, indicates either that many gastric ulcers are entirely overlooked clinically or, which is improbable, that many diagnosable duodenal ones heal without resultant scar formation.

In spite of the facts, however, that some peptic ulcers are symptomless and heal naturally, most of them produce a characteristic type of indigestion that tends to persist intermittently over long periods of time, and some of them lead to the development of serious complications. Furthermore, though satisfactory healing, with or without treatment, may take place, recurrences of activity are common. For these reasons it is necessary that in all diagnosed cases some definite form of medical management be instituted.

THE PSYCHIC FACTOR IN TREATMENT

The psychogenic factor in the etiology of peptic ulcer, as in many other affections of the digestive tract, is receiving a great deal of attention at the present time, due in part perhaps to the emphasis that is now being placed on psychosomatic medicine in general. It has been claimed, for instance, that disturbance of the emotional centers in the brain, acting through the hypothalamus and the autonomic nervous system, set up motor and secretory changes in the stomach, and also that by the same paths they sensitize its nervous mechanism and so lead to vasomotor reactions with ischemia (believed by some to be an important factor in the production of ulceration). Irrespective of the significance of such a theory as to the pathogenesis of ulcer, it is certainly true, with regard to its management, that when the ulcer patient puts himself in the hands of a competent, sympathetic and understanding physician, transfers to him his personal concern about his condition and cooperates with him in every detail of the management, the first great step toward recovery has been taken.

The ideal relationship between the doctor and his peptic ulcer patient does not develop spontaneously, although some physicians, by virtue of their personality, their reputation for competence and their ability quickly to understand and to adjust themselves to the patient's mental and emotional reactions, are able almost at once to secure his complete confidence and cooperation. More often this cordial and beneficial relationship develops only as a result of a conscious and meticulous effort on the part of the physician. That involves at least a careful, painstaking study of the case and the institution as promptly as possible of some form of management, however simple that may be.

The mere fact that the patient is made to feel from the beginning that his physician is interested, not only in him but also in his disease, and that his case is receiving personal study and treatment, is most important psychologically, and this is doubtless the explanation for the success of many varieties of therapy, whether rational or not and whether prescribed by a physician or a cultist.

An exhaustive investigation of the patient's disease condition, therefore may be regarded not only as essential to the physician in order that he may make a correct diagnosis and outline an intelligent program of therapy, but also as an actual part of the management of the case. It should include, besides a carefully elicited and detailed account of all the complaints, whether strictly gastro intestinal or not, and a meticulous examination of the entire body, at least the following special studies: a gastric analysis, a complete roentgenologic study of the digestive tract, an inspection of the feces, especially for blood, and sometimes, if the lesion is in the stomach, a gastroscopic investigation. If also, at the first visit, the patient is put on some simple dietary program, often only frequent feedings of a nonirritating diet, his thorough cooperation usually will have been secured by the time the diagnostic procedures have been completed and indeed his symptoms may, even before that time, have entirely disappeared. Even so, however, although no additional specific therapy may be required the patient should, at least for psychological reasons be kept under general observation and re-examined by a roentgenologist from time to time until all objective signs of activity have disappeared.

INITIAL MANAGEMENT OF THE AVERAGE CASE

For the sake of simplicity I shall now outline my ideas regarding the more specific aspects of peptic ulcer therapy dealing mainly with the average case that can be managed on an ambulatory basis, but also briefly with the more severe and the complicated cases that require hospitalization and more carefully controlled supervision.

Every patient suspected of having an ulceration of the stomach or duodenum unless it is contraindicated by a complication should have a prompt roentgenologic examination for exact diagnosis, and the treatment should be based in the main on the observations so made together with the history of the case. The physical examination and the gastric analysis are of secondary importance, and unless tenderness and rigidity or blood in the gastric contents are found, usually do not influence the type of therapy. In the average case without a complication, and even irrespective of the degree of discomfort, an ambulatory program may safely be given a short trial. It should include primarily measures designed to relieve discomfort or pain, to put the patient at ease mentally and physically, and to supply him with a diet adequate in all respects.

In some instances, even when the roentgen study has been essentially negative or at least shows no typical defect, the history may be so suggestive as to justify the diagnosis and a period of treatment, and always, irrespective of the patient's story, when an ulcer crater, either gastric or duodenal, with indirect signs of activity, is demonstrated roentgenologically, a detailed program of therapy should be outlined and insisted upon. This should be presented clearly and forcefully from the very beginning, with emphasis on the points that the patient has a chronic disease, that, though the symptoms may clear up readily, recurrences are common, that the lesion may last a long while after the symptoms have disappeared, even after the roentgen ray shows no further evidence of the ulcer, and that throughout his life he must insofar as possible avoid undue physical and mental fatigue, emotional crises and infections. It is also worthwhile, I think, to stress the facts that we do not know the exact cause of the disease, that no special medicinal preparation has been proved of value in its amelioration and that the ultimate result depends largely on the patient's cooperation in a regimen that involves various alterations in his habits of life.

1. Relief from Pain.—Relief from discomfort or pain, whether mild and of a very transient nature or severe and more or less continuous with exacerbations when the stomach is empty, is the first essential of treatment and is ordinarily obtainable merely by the proper use of a bland, nonirritating diet. A mixture of milk and cream has proved its value over a long period of time and may be depended on entirely for the first few days, though I have usually obtained equally satisfactory results by including gelatin preparations, creamed soups, pureed vegetables, noncellulose-containing cereals, plain crackers with butter, cream cheese or jelly, eggs and simple desserts. These substances, however, to be effective in the relief of pain must be administered in small quantities and at frequent intervals, usually every two hours throughout the day, sometimes hourly, and occasionally even during the night. Rarely have I found it necessary in the ordinary case to give any drugs, though at times an alkaline mixture may be required for the first day or two. My experience with the antispasmodics has been very disappointing. Sedatives, such as the barbiturates, however, are frequently of great value, and should be used freely until the patient is adjusted to his new regimen of life.

When the patient becomes entirely comfortable throughout the twenty-four hours, which may be within a few days or only after a week or more, the intervals between feedings may be prolonged, usually so that he gets only six feedings a day, three at his regular meal-times with an intermediate one in the midmorning, in the midafternoon and at bedtime. Such a dietary program should be continued for three or four weeks (only two weeks in the case of a gastric ulcer) and then the patient should have a second roentgen examination.

2. Relief from Physical, Mental and Emotional Strain—Meantime during the preliminary period of treatment and perhaps most important from the viewpoint of ultimate recovery the routine of the patient's life should be so altered as to relieve him of all physical mental and emotional strain. The need for physical relaxation is fully appreciated in connection with all types of acute and chronic illness, but in spite of the emphasis that has been placed on it by all authors, it is not so well understood that mental anxiety and emotional stresses of every kind interfere equally with the healing of peptic ulcer. Since, as already stated, it has been demonstrated that mental reactions, including the emotions, directly affect certain gastric and intestinal functions, one has scientific justification for focusing attention on these factors. Anyway, every experienced physician knows that peptic ulcer develops most readily in persons who are highly keyed nervously, are intense, meticulous and worrisome, often sleepless easily fatigued and subject to emotional crises, also, that when the patient with an ulcer goes on a vacation, relaxes in his work or suddenly is able to resolve his business or domestic problems he begins to improve. On this purely empirical basis it is clear that freedom from emotional stress and mental tension is always indicated as a therapeutic procedure.

The accomplishment of such an alteration in the patient's way of life is often the most difficult aspect of the therapy, and yet the wise counsellor can sometimes bring it about merely by a frank explanation of the situation or by outlining in detail and firmly insisting on, a less strenuous attitude in the patient's business social and domestic relationships. Only rarely, if the physician himself understands the situation and has the necessary patience and ingenuity need he seek the assistance of a psychiatrist. In some instances, however, that is highly important.

3 Adequate Nutrition—Finally, among the fundamentals of treatment for the average case of peptic ulcer, is that of supplying him with an adequate diet, including the necessary vitamins and minerals. Although incidentally an improvement in the nutrition of the patient, as indicated by some gain in weight is usually accomplished by his frequent feedings the concentrated food substances that are prescribed and his freedom from nervous strain, already discussed this is not ordinarily regarded as a primary aim of the treatment. I believe it should be. I believe also that a mere gain in weight is not enough that may occur in the absence of a sufficiency of vitamins, perhaps also of minerals. The Sippy diet is known to be deficient in thiamine and ascorbic acid and yet patients may gain weight on it. This is a special reason for including additional food substances, such as the green vegetables and fruit juices even meats, reasonably early in the management or at least for adding some of the synthetic vitamins.

We have long appreciated that a certain constitutional type of in

dividual is most prone to ulcer formation the thin, hungry-looking, lantern-jawed, gastric-hyperacid type. Heredity has been assumed to be the important factor in the production of this constitutional type, but may it not be that heredity, like family influences, is effective mainly in that it determines certain food habits, a worrisome disposition and a sensitive, vagotonic gastro-intestinal tract? If so, it is not fair to say that we can do nothing about constitutional and hereditary influences, because, if we are patient, specific in our directions and forceful enough, we often can change the food habits, sometimes alter the mental reactions and, at least to some extent, control the secretory and motor disturbances of the stomach. At any rate, by such means, we not infrequently can greatly improve the nutrition of the subject, and in so doing it may be that we are approaching the matter of treatment in a truly rational way.

Data are rapidly accumulating to show that experimental wounds heal best when the nutrition is adequate, especially when the food contains an excess of proteins and vitamins, and that many skin and mucous membrane lesions disappear most readily when certain vitamins are administered. One need cite only the results in the typical lesions of pellagra in support of this contention. Furthermore, the modern treatment of the bleeding peptic ulcer (the Meulengracht program), which involves the prompt administration of an adequate diet, brings about healing far more readily than the older starvation regimen. One wonders, therefore, if the success of many of the modern treatments of simple ulcer is not due more largely to the fact that they include an adequate diet than to the fact that they happen to neutralize the gastric acidity, to coat the stomach wall, or to eliminate the harmful effects of tobacco, of certain endocrine disturbances, or of distant focal infection.

The fundamental points then that I wish particularly to emphasize in the treatment of the average uncomplicated and ambulatory ulcer patient are (1) that he be relieved of his discomfort, (2) that he secure freedom from physical, mental and emotional strain, and (3) that he get an adequate diet, with special reference to its protein, vitamin and mineral content.

ADDITIONAL POINTS IN THE MANAGEMENT OF THE AVERAGE CASE

Other factors commonly mentioned in connection with the etiology of peptic ulcer, however, deserve more specific consideration from the viewpoint of therapy. Although I do not regard any of these as of primary importance, each has a bearing on one or more of the therapeutic principles already discussed and its neglect may seriously retard ulcer healing.

1 **Gastric Acidity**—It is generally believed that the acid character of the stomach contents is a factor in the production of peptic ulcer,

chiefly because such a lesion does not develop in the achlorhydric stomach and because a hyperacidity is frequently found in association with ulcer, especially in the patient with a duodenal lesion. On the other hand, many subjects of hyperacidity never develop an ulcer and some believe that when a hyperchlorhydria does occur in the ulcer patient it is a secondary phenomenon. In any event, it does not follow that a peptic ulcer cannot heal when the gastric contents are acid, which is their normal reaction. It would be an unusual phenomenon in nature to require that a normally physiologic state be radically altered in order to bring about recovery from a diseased condition.

Clinically, as a matter of fact, we do know that peptic ulcer can heal in the presence of an acid reaction of the stomach contents, since this often occurs spontaneously and also when the ulcer is under a program of treatment that includes no measures designed completely to neutralize the gastric acidity. Indeed, it has been shown by Wosika and Emery¹ that, even when the Sippy program, including alkalies, is strictly enforced, the free acidity is reduced on the average only two clinical units below that obtained by the food alone. My experience also indicates that the ordinary regimen, including alkalies, does not usually bring about a complete neutralization of the gastric acidity. Furthermore, as Karr and Abbott have shown, unless the alkalies are given in very large dosage they tend to increase gastric evacuation, thus removing the food material that in itself is nature's neutralizing agent. The alkalies, therefore, tend to counterbalance the advantages of the addition of extra cream to the milk in the Sippy program, said to be due to its slowing up of gastric evacuation (presumably by stimulating the elaboration of enterogastrone).

Some reduction in the degree of the acidity of the gastric contents, however, does seem desirable in the management of peptic ulcer and this doubtless is the reason that the patient often instinctively develops the habit of taking extra feedings. Nature seems to indicate what he needs, since the characteristic pain is gnawing or that of hunger. Under normal conditions the acidity of the stomach contents rises and falls throughout the day, the fall occurring chiefly as a result of the intake of food, some food substances being more effective in this respect than others. It would seem reasonable therefore if one wishes to keep the acidity at a lower level to employ nature's own method rather than the use of alkalies, selecting however, the most effective foods and administering them at sufficiently frequent intervals to maintain comfort. After all, our habit of eating only three times a day is artificial, it is by no means the custom in all countries.

The antacids, however, are sometimes helpful in the management of certain very active cases of ulcer, those with an unusually high acidity in order quickly to bring the pain under control, but I have

rarely found it necessary to continue their use for more than a few days. When employed over longer periods, beyond the time that food alone will control the pain, I have not found that they speed the healing process or tend to prevent ultimately a recurrence of activity. Furthermore, it has been shown that secondarily they actually tend to increase the gastric acidity and to interfere with the appetite—even in some instances to produce an alkalosis and renal stones. I have encountered patients who had been on an ulcer program for a long time, including alkalis, and who were discouraged, losing weight, having difficulty in taking their prescribed food and complaining of headache—all of these phenomena disappearing soon after the discontinuance of the alkaline medication and without other change in the regimen. Sometimes this has occurred when no alkalosis could be demonstrated chemically.

If the antacids are to be used at all, I prefer aluminum trisilicate or magnesium hydroxide, or even better a combination of these preparations, such as *gelusil*, which is a buffer substance and not a true alkali. Essentially, however, it seems to me unphysiologic markedly to disturb the acid character of the gastric contents, which plays such an important role in peptic digestion and the destruction of bacteria in the stomach and which influences both the secretory and motor functions of the intestines.

Unfortunately, no exact data on comparable groups of cases treated continuously with and without alkalis are available, but Dick and Eisele² have recently reported that, in forty-one cases treated by milk and cream feedings at hourly intervals and without either alkalis or night aspirations, the mean time of crater disappearance, as demonstrated by roentgen examination, occurred in 86 per cent within seventy-five days, in half of them within thirty days. Furthermore, only very occasionally have we in our clinic during the past twelve years used any neutralizing medication beyond the first week, and yet our results, I believe, have been at least as good, perhaps better, than previously when we followed a program that included the free use of the alkalis throughout the period of ulcer activity.

2 Infection—It is not obvious clinically that peptic ulcer develops as the result of either acute or chronic infection, or even in relation to focal infection, and yet a recurrence of activity not infrequently has been observed to follow an acute infection, especially of the upper respiratory tract, and sometimes improvement has followed the eradication of a focal infection. One naturally wonders if such infection does not act by undermining the general health and resistance of the patient, rather than as a specific factor. In any event, from the viewpoint of management, it would seem clear, as in the presence of any disease condition, that all focal infection should be carefully searched for and eliminated and that every person with an ulcer, active or inac-

tive, should meticulously avoid insofar as possible contact with those suffering from an acute respiratory infection and should take extra precautions, when afflicted with a general infection of any kind, to assure himself a carefully selected and nutritious diet, taken at frequent intervals

3 **Hormonal Influences**—Recent investigations, chiefly of an experimental nature, seem to be preparing the way for a therapeutic trial of various hormones in peptic ulcer. The work of Ivy, Quigley and their associates with enterogastrone, which in the presence of fats is liberated by the intestinal mucosa, is particularly encouraging. They have showed that it depresses both gastric secretion and motility. Likewise Sandweiss and his associates³ have isolated from human urine a hormone that, through some primary action in the intestine, brings about changes in the gastric mucosa that benefit the healing of experimental ulcer in the dog. Although this substance also is a gastric secretory depressant, they believe that its significant effect on ulcer healing is due to stimulation of fibroblastic and epithelial proliferation and the formation of new blood vessels in the stomach wall. They claim encouraging results in a series of sixty-three chronic duodenal ulcer cases in the human. As yet, however, neither of these substances has been given a sufficient clinical trial to justify its further discussion in this presentation.

4 **Personal Habits**—The personal habits of the ulcer subject are more amenable to regulation, and doubtless for this reason have received a great deal of attention from the profession. It is probable, however, that their importance depends on whether or not they are prejudicial to the patient's general health. As in any disease condition, particularly when the nutrition is disturbed, every effort should be made to avoid physical fatigue, to secure some outdoor recreation, to get plenty of sleep and to be temperate in the use of stimulants.

Because of the location of the lesion it is particularly important in the ulcer case that all food and drink that may be irritating either mechanically or chemically should be avoided. One should therefore forbid the use of the *coarser food substances*, those that cannot be thoroughly macerated, even liquefied in the mouth, because of their possible mechanical irritation, and also forbid the use of the highly acid foods and the condiments, because of their chemical irritation. In the proscribed list of foods should be placed the more fibrous vegetables, raw fruits except perhaps orange juice, all fruit seeds, skins and pulp, salads, whole wheat breads and nuts. I have observed a severe reaction, even with hemorrhage in a previously quiescent ulcer after the ingestion of peanuts, presumably due to the lodgment in the ulcer crater of small pieces that cause chemical irritation, such as occurs in the lung after their inhalation.

Whether or not *tea* should be allowed is still an open question, but personally after the first week or two in a patient who is doing well I

have not hesitated to include it, particularly because of its content of protein and vitamins, and without obvious disturbance. Although the meats do tend to increase the gastric secretion, at the same time they neutralize the acid readily and also increase the patient's desire for other foods.

In this connection it is most important that the eating habits be regulated—that the patient eat deliberately and only when he is mentally at ease, that his food be thoroughly chewed, and that he expectorate such particles as cannot be liquefied in the mouth. This suggests also that he should have good dentures and make good use of them.

The use of *tobacco* has caused considerable controversy, and the general opinion is that smoking should be strictly forbidden. Certain evidence suggests that it increases the acid secretion of the stomach, but whether or not that occurs in the human subject on an adequate diet has not been determined. To argue that the recent increase in the sale of cigarettes is responsible for the present increase in the incidence of ulcer is hardly justifiable, in view of the many other factors that may be involved. Nicotine does, however, increase vasomotor tone, a possible factor in ulcer production, and on that basis it would seem wise in the ulcer case to restrict its use. On the same basis, however, *alcohol* might be advised, since it relaxes the tension in blood vessels. In spite of this pharmacological observation, there are good clinical reasons for avoiding the use of alcoholic beverages. Most clinicians have observed flare-ups in a quiescent ulcer after the ingestion of alcohol, probably due to its directly irritating qualities. Also, it may have an injurious effect because it leads to careless eating habits, especially to rapid eating, insufficient chewing and an indiscriminate selection of food substances.

LATER MANAGEMENT OF THE AVERAGE CASE

After two weeks in every case of demonstrated gastric ulcer, and after four to six weeks in that of a duodenal ulcer, another careful roentgenologic examination should be made. In the former instance, unless by that time the crater is obviously smaller and the patient's symptoms have entirely disappeared, he should be hospitalized for a more intensive program of diagnosis and therapy or he should at once be subjected to surgical intervention, because of the possibility that the lesion is malignant. Operative interference is particularly indicated if the pylorus or greater curvature of the stomach is involved, if the defect, after two weeks, is not obviously smaller, and if a gastroscopic investigation is not convincingly in favor of the lesion being benign. At times, even when the middle third of the lesser curvature is involved, where malignant lesions are much less common, further medical treatment is not justified. In the case of a duodenal ulcer, however, even if no decrease in the size of the crater can be shown, further conservative

therapy is usually safe, but if, after a month, the symptoms have not entirely cleared up I believe it is best at least to hospitalize the patient for a more strict program of treatment.

Consequently, in the case of a gastric ulcer that is objectively showing a favorable response to ambulatory therapy and in the case of the usual duodenal ulcer that is symptom-free after two to four weeks, a continuation of ambulatory management is justified. This need not be altered markedly from that already described, but in most instances the restrictions on the diet may be relaxed somewhat, the softer green vegetables no longer need be purged, some of the less acid fruits, uncooked, may be permitted, and, if night feedings have been necessary for the relief of discomfort, they may be omitted. Intermediate feedings during the day, however, should be maintained for another month or two, depending on the patient's general progress and his response to their omission from time to time. The other items of therapy, especially freedom from mental and emotional strain, a fully adequate diet, abstinence from alcohol and the excessive use of tobacco, and meticulous care as to the habits of eating, should be maintained indefinitely. Eventually also, after further roentgen investigation and the disappearance of all signs of activity, the intermediate feedings may be entirely omitted, but the patient should be ready to go back to them immediately if subjected to any special strain in life, to physical fatigue or to infection of any kind. Only by such a prolonged regimen of prophylactic therapy may one expect to avoid a recurrence of ulcer activity.

Subsequently, for at least two years, and no matter how well the patient seems to be, he should report to his physician from time to time for a review of his progress and, on any recurrence of ulcer symptoms, he should have another roentgenologic examination.

MANAGEMENT OF THE MORE SEVERE CASES

In the foregoing paragraphs I have referred to occasional developments in the average ambulatory case that demand a more radical form of therapy—the failure of certain gastric lesions quickly to show signs of healing and the persistence of symptoms in certain duodenal cases. In addition, some cases present such severe symptoms from the beginning as to indicate a need for continuous observation and some although they seem to be doing well for a time, develop a recurrence of symptoms suggesting reactivation. In all these cases as well as in those with complications, to be discussed later, hospitalization is clearly indicated. Except in those with a definite complication and in those that demand prompt surgical interference because of the possibility of the complication of malignancy a strict medical program is required.

Such a regimen should include bed rest, a carefully supervised dietary, in some instances limiting it to milk and cream feedings, the appli-

cation of moist heat to the epigastrium and the use of antispasmodics for the relief of pyloric spasm, the administration of mild sedatives and the inauguration of a deliberate plan to free the patient of anxiety, fear, or whatever psychological disturbance may be present. In some instances, even the use for a short time of alkalis or at least of antacids of some kind may be indicated. Some authors advocate in the more resistant cases a continuous drip of aluminum hydroxide, even throughout the night, but I have not found that procedure of any special value. I shall not discuss the details of such hospital management further at this time, since my interest here is primarily in the average ambulatory case, but would point out that, on such a program, in many of the cases the severity of the symptoms will quickly subside, so that subsequently they can be managed as ambulatory cases. When they do not do so, they are regarded as refractory and so are commonly regarded as candidates for surgical intervention.

MANAGEMENT OF THE COMPLICATIONS

The clinically important complications of peptic ulcer are perforation, hemorrhage, stenosis and malignant degeneration. Of these, perforation is primarily surgical, the internist having no immediate responsibility beyond making the diagnosis promptly and putting the patient in the hands of a competent surgeon, the subsequent medical management deserving no attention in this presentation.

I. Hemorrhage.—Hemorrhage, the second complication, however, is as strictly a medical problem, in my opinion, as is perforation a surgical one. The results from the medical management of bleeding peptic ulcer are now so satisfactory that only in the rarest instances is there any justification for an immediate surgical consultation, and that when some additional complication is suspected. Later, when the bleeding has ceased, operation is frequently indicated, especially if more than one hemorrhage has occurred. This aspect of the situation also I will not discuss further in this paper.

The prompt-feeding regimen for the treatment of bleeding ulcer, advocated by Lenhart, by Andresen and, in 1934, by Meulengracht,⁴ has been adopted in many clinics throughout this country. The results, as tabulated in a recent report by Rasberry and Miller,⁵ are far better than have been published for any single group of cases treated by other methods. In 1938 Miller and Elsom⁶ assembled data on 5843 reported cases of gross bleeding treated by the previously accepted starvation program that showed a mortality of 8.7 per cent, several groups as high as 15 to 25 per cent. In a collected series of 383 cases treated surgically they found a mortality of 28 per cent, the lowest being 5.9 (Finsterer, who operated on all his cases early, irrespective of the degree of hemorrhage). Rasberry and Miller, on the other hand, found in a series of 2111 promptly fed cases collected from the literature, and including

seventy-five of their own, that the total mortality was only 4 per cent, and on further analysis discovered that many of the cases in which death occurred should be eliminated, because of coincident perforation pneumonia, carcinoma or cardiac disease, or because the patients were moribund on admission to the hospital and could not have been saved by any type of therapy. Eliminating such cases they got a mortality of 1.9 per cent for the total series.

It is inevitable that death will occur in a few cases of bleeding ulcer, usually those in older people who have a large, open, sclerotic vessel in the base of the ulcer, but, on the basis of the analysis referred to, it would seem that the number is exceedingly small surely far less than would result if surgery were employed in all of the severe cases. Furthermore it would seem possible to explain the lessened mortality in the promptly fed cases, as compared with those treated by starvation, on the basis of an adequate diet, which maintains the nutrition of the patient throughout the period of shock, of a sufficient fluid intake, which also combats shock, and of freedom from anxiety, which has been a marked characteristic of all the cases treated by prompt feeding. An additional factor in my opinion is the fact that when the patient is fed it is rarely necessary to use morphine, which has a tendency to keep the gastric and duodenal musculature relaxed. Whatever the explanation, the present results seem definitely to justify the so-called Meulengracht regimen.

This program involves immediate feeding even in the midst of the hemorrhage and persistence in the feeding irrespective of developments. The food should be given at least six times a day. Although Meulengracht gave ground meats as well as vegetable purées, bread and butter, oatmeal and tea, the principle of his program was the immediate feeding and not a specific sort of diet. We have not felt that the type of diet need be different from that we ordinarily use in ulcer cases, and some authors have reported using only milk and cream. Witts² has emphasized the importance of including an adequate amount of fluid by mouth and of giving transfusions as indicated by the general condition of the patient. We have also done those things and have in addition insisted that no morphine be administered, using instead sodium luminal as required for the comfort of the patient.

On such a program the bleeding may continue for some days but since the patient is comfortable, is not in shock, and the blood loss can be cared for by transfusions, one should not lose confidence in the regimen. Eventually in almost all cases (all but one in our series of seventy-five) the hemorrhage eventually ceases. Several deaths have been reported when the program was stopped because of the continued bleeding and the patient put on starvation. Such instances of course should not be regarded as deaths on the feeding program.

2 Stenosis.—Pyloric stenosis, if of permanent organic nature is a

complication that must be handled surgically. In many instances, however, the obstruction is due to some medically remediable condition, such as edema or spasm. The patient must be kept under observation at least until the nature of the obstructing lesion is determined. In all of the cases, therefore, that show obstruction by the roentgen ray, the patient should be hospitalized and put on a simple medical program designed to relieve gastric retention and to promote evacuation through the pylorus. This of course necessitates the use of a fluid diet, administered in small amounts and at frequent intervals, and some muscle relaxant, such as belladonna, novatropine, or syntropan. Hot applications over the epigastrium at times seem very helpful. Also, because of the possibility that the obstruction is due to edema rather than spasm and that the edema is dependent on hypoproteinemia, a determination of the blood plasma protein concentration should be made at once. If the figure is low, blood transfusions or plasma injections are indicated. Ideally, one would like to be able to pass a tube through the pylorus to the jejunum and give protein feedings, but usually that is impossible because of the degree of the stenosing lesion.

If the edema is on an inflammatory basis it often is helpful to intubate the stomach, leaving the tube in place, and to aspirate completely the gastric contents about two hours after each feeding. In this way the stomach is never allowed to become distended, fighting peristalsis is avoided, and at the same time, some nourishment usually gets through to the bowel where it can be absorbed. As a matter of fact, such a procedure allows one to judge from time to time to what extent, if any, the obstruction is subsiding. It often subsides completely, and then the patient can be managed in the usual way.

3 Malignancy—The complication of malignant degeneration in a peptic ulcer does not concern us fundamentally in this presentation, since the mere suspicion of such a change is always an indication for prompt surgical removal of the affected area. The only point that I need emphasize, therefore, is that no form of medical treatment is justified once the diagnosis of malignancy has been made or even is suspected. Fortunately, however, only gastric ulcers become malignant and a relatively small percentage of them, perhaps not more than 5 to 10 per cent. Palmer⁸ doubts if any peptic ulcer, primarily benign, ever develops this complication, believing that the malignant ones are so from the beginning.

In any event, malignant ulcer of the stomach, with roentgenologic signs that cannot be differentiated from those of a benign lesion, does occur, and so in treating every gastric ulcerative lesion, the possibility of malignancy must be borne in mind. It is for this reason that the management of the gastric ulcer must be different from that of the duodenal one. Every such gastric case should be re-examined roentgenologically after two or three weeks and, unless all the indications

are then favorable, the patient should be hospitalized for another short period of medical therapy, on a stricter basis, and for a gastroscopic examination. Unless the latter investigation and a third roentgen study clearly suggest that the lesion is benign, he should be subjected to surgery. In any event, he should have other roentgen studies from time to time, and in some instances additional gastroscopic investigations, until the lesion has healed.

FUNCTIONAL DISTURBANCES OF THE ALIMENTARY TRACT

WALTER LINCOLN PALMER, M D , Ph D , F A C P *

PERHAPS the most frequent complaints encountered by the general practitioner are those arising from functional disorders of the digestive system. These may be localized to certain sections of the alimentary tract, but Alvarez¹ has very properly pointed out that there is usually an underlying hyperirritability of the entire digestive tract, and as a rule a hypersensitive individual as well. None of the diagnostic terminologies used to describe these symptoms are entirely satisfactory, but on the other hand any name suffices if its limitations and connotations are properly understood. Some of the more frequent and more or less synonymous terms are nervous indigestion, spastic colitis, mucous colitis, functional colitis, irritable colon, irritable bowel, unstable or unhappy bowel or colon. White, Cobb and Jones² prefer the designation mucous colitis, pointing out that the syndrome was described in detail with great accuracy by Da Costa in 1871 and also that the original meaning of the word colitis was "disorder of the colon" rather than "inflammation." The monograph published by these workers in 1939 is a classic.

DIAGNOSIS

The symptoms of gastro-intestinal irritability are numerous and quite varied both in type and in severity. One may list belching, heart burn, bloating, abdominal distention, abdominal soreness, pain, anorexia, constipation and diarrhea as the more frequent complaints. Unfortunately, they are not pathognomonic of simple hyperirritability. Frequently such symptoms are the manifestation of a disturbed mental state or of organic disease outside of the digestive tract such as thyrotoxicosis or pulmonary tuberculosis, more frequently perhaps they serve to mask the presence of intra-abdominal lesions such as carcinoma. Consequently care should be taken to note symptoms not compatible with a functional disturbance and efforts should be made to exclude organic disease. The armed services have learned the importance of routine fluoroscopy of the chest, first demonstrated in civilian medicine.^{3, 4} There is evidence that in time patients with dyspeptic complaints will receive routinely not only a fluoroscopy of the chest, but also of the esophagus, stomach and intestine. This will be a great forward step.

From The Frank Billings Medical Clinic, Department of Medicine, University of Chicago, Chicago

* Professor of Medicine, School of Medicine, University of Chicago, Attending Physician, Albert Merritt Billings Hospital

Gastro-intestinal Discomfort and Pain—In spite of the fact that there is no pathognomonic sign of hyperirritability of the digestive tract there is nevertheless a quite definite syndrome—a group of symptoms, certain physical findings, and a disturbance of bowel function, more or less characterizing the condition. For instance, belching while it occurs in normal individuals and in patients with various diseases, is usually a functional disturbance. Abnormal belching as a rule means abdominal discomfort which the patient attempts to relieve by swallowing and regurgitating air. A cure is best effected by explanation of the mechanism and relief of the discomfort which led to the formation of the habit.

This discomfort is rather typical of hyperirritability of the bowel. It tends to appear while eating or immediately after eating. If present before eating it may be aggravated by food taking or it may be relieved thereby, thus simulating peptic ulcer. The sensation is often one of distention—a feeling as though an enormous meal had been eaten whereas in reality only a small amount has been taken. The patient may have come to the table hungry and found that a few mouthfuls sufficed, or a regular meal may have been consumed to be followed not by a feeling of satiety but of acute discomfort and abdominal soreness, an unpleasant awareness of the abdomen. The localization of the distress is variable, frequently it is generalized, often it is upper or lower abdominal; sometimes it is localized to one of the lower quadrants. The patient attributes the discomfort to 'gas' or a "pocket of gas" which seems logical to him for it may be relieved temporarily by belching by the passage of flatus or by rumbling and gurgling in the abdomen.

When the distress is more intense it tends to more precise localization in the lower abdomen and is interpreted by the patient as pain often shifting from one point to another but frequently persisting tenaciously in one spot. When constant the pain is a continued acute soreness or a more severe intermittent cramplike pain. The relationship to a bowel movement may be significant in that usually the pain is relieved thereby. There are cases however in which defecation precipitates pain. These abdominal sensations all seem to arise from a lowering of the visceral pain threshold perhaps from a true "soreness" with spasm and perverted muscular contractions. The cramps induced by a defecation contraction seem obviously attributable to spasm in the colon. Heartburn has been shown to be related to peristalsis and spasm in the lower esophagus.⁴ Similarly substernal tightness, fullness and discomfort on swallowing may be related to spasm in the upper part of the esophagus. Loss of appetite and hunger may be related in part to a cessation of the normal contractions of the resting stomach and intestines, while nausea seems attributable to reverse peristalsis and a reversal of the normal gradient.⁵ These phenomena are frequent

usually transitory and only rarely lead to vomiting or to loss of weight

Physical Findings—The physical examination usually discloses some tenderness of the colon on deep palpation. As a rule this is most noticeable in the left lower quadrant where the lower descending colon and the sigmoid may be rolled under the palpating fingers as a tender contracted tube. A loop of sigmoid in the right side of the pelvis may result in tenderness there. The sensitive transverse colon can generally be palpated in the midabdomen as it crosses the spine. The abdomen may be distended and tympanitic with excessive rumbling and gurgling noted on auscultation.

Character of the Stools—The third important feature of the syndrome is the objective evidence of bowel dysfunction afforded by the description of the stools. The patient's statement that he is constipated is significant but not trustworthy, for upon questioning one may find it to mean merely that the patient *thinks* he requires cathartics or enemas in order to avoid becoming constipated. Rarely do such patients leave their bowels alone long enough to ascertain whether they would function normally or not. However, many patients who are not cathartic or enema addicts nevertheless have hyperirritable digestive tracts. Some consider themselves constipated, others recognize the presence of a tendency to diarrhea. The significant feature in all is the fact that bowel function is altered to some extent, it is rarely normal.

For practical purposes, the normal defecation is considered as a well formed collection of feces an inch or so in diameter, several inches in length, and firm in consistency. True constipation exists when the fecal material is retained in the colon so long that excessive water absorption occurs with the result that the feces are passed as hard dry balls. This may result from atony or insufficient muscular activity, but much more frequently it is produced by excessive spasm. The presence or absence of pain gives an important clue in this differentiation, for pain usually means spasm. Equally significant is the passage of formed fecal material of small diameter, a caliber of an eighth to a quarter or perhaps half an inch, simulating the so-called lead pencil or ribbon-like formation of lead poisoning. Frequently the narrow caliber is erroneously attributed to a neoplasm of the sigmoid or to spasm of the anal sphincter, it is almost pathognomonic of spasm of the sigmoid.

Soft unformed or watery dejecta are indicative of hypermotility of the bowel, the material traversing the colon too rapidly to permit the proper absorption of water. Mucus is secreted throughout the digestive tract in response to irritation—the greater the irritation the more mucus. In some individuals so-called "mucous casts of the bowel" may be expelled. These consist merely of long shreds of dried and tenacious mucus. In some patients the intestinal hyperactivity is mani-

festated also by an excessive passage of flatus. The odor and color of the feces are not of diagnostic significance.

Superimposition of a Functional Disturbance Upon an Organic Disease—The diagnosis of a functional disturbance of the digestive tract is thus based upon such a syndrome and the reasonable exclusion of organic diseases, although the syndrome may be superimposed upon organic lesions. Thus the so-called *gallbladder dyspepsia* is in large measure at least such a functional disturbance occurring in an individual found to have gallstones. Cholecystectomy characteristically relieves biliary colic,⁷ the dyspepsia usually persists. In some instances the digestive symptoms may disappear following operation regardless of the procedure, be it cholecystectomy, gastro-enterostomy or something else. Conversely the so-called gallbladder dyspepsia may be relieved by the measures usually employed in treating a functional disorder and disregarding the gallstones, such a program, however, does not influence the biliary colic. In the so-called chronic non-calculous cholecystitis the symptoms seem attributable not to the gallbladder, but to the intestine, for they tend to persist after cholecystectomy and on the other hand may be relieved medically without cholecystectomy.⁸ This fact seems to negate rather than support the concept that the symptoms in such cases are due to functional disorders of the gallbladder and biliary tract with spasm of the sphincter of Oddi. Fat intolerance is not a problem, for as a matter of fact it is not as characteristic of or as peculiar to gallbladder disease as it is generally considered.

This criticism of the concept of gallbladder dyspepsia applies equally well to *appendiceal dyspepsia* and so-called chronic appendicitis. Acute appendicitis and appendiceal colic are of course appendiceal in origin and call for appendectomy. So-called "appendiceal dyspepsia" or "chronic appendicitis" may also be relieved by appendectomy or by any other procedure, more frequently it persists and may be relieved medically by management as a functional disturbance of the bowel.

The more acute attacks of intestinal colic resulting from dietary indiscretions in individuals with hyperirritable digestive tracts simulate and indeed often cannot be differentiated from *staphylococcal food poisonings* or mild *salmonella infections*, although in the usual case the presence of fever, the suddenness of the onset and the severity of the illness serve to identify the attack. Occasionally one sees nausea, vomiting, abdominal pain and distention suggestive of paralytic ileus but subsiding rapidly as the irritability of the gut decreases.

ETIOLOGY

The etiologic bases for hyperirritability of the digestive tract are of two general types, the physiologic and the emotional or psychologic.

In the *physiologic* group the cathartic and enema habitués are conspicuous. Of course, it can be argued by those psychiatrically inclined that in these individuals the problem is not purely physiologic, for is not the habituation psychologically determined? Thus may be the case. It is also to be noted that many people use cathartics regularly for years without developing abdominal distress. Nevertheless, waiving for the moment the psychologic aspects of the problem, it is a fact that cathartic habitués with chronic abdominal discomfort and pain may be relieved of distress by teaching them to discard the habit and to regulate the bowels with diet alone.

Another large group of so-called dyspeptics are those who regularly indulge in dietary indiscretions or whose food habits lead them to consume a more laxative diet than they are able to tolerate. The irritating action of certain foods such as molasses, beer and cider are well known. All foods are more or less laxative, none are actively constipating. Some individuals habitually consume excessive amounts of irritating foods. Coffee is an intestinal stimulant and when used to excess may produce both distress and small calibered spastic bowel movements. Nicotine is likewise a stimulant of intestinal activity and seems to be responsible for many cases of "chronic indigestion."⁹ Alcohol is also rather irritating. Schindler and Gray¹⁰ and Berry¹¹ were not able to ascribe the morning nausea of the chronic alcoholic to gastritis, perhaps it is attributable to intestinal irritation.

Specific food idiosyncrasies and allergies doubtless exist in certain individuals, particularly for shell fish, raw eggs, and strawberries. Usually these allergic states produce in addition to the digestive disturbances urticaria or other reactions affording evidence of their true nature. It is of course possible that chronic allergic digestive disturbances may exist without such manifestations, but in most patients the mechanism seems more probably to be that of simple irritation. The results of so-called elimination diets must be appraised cautiously.¹²

The *nervous* or *emotional* component in digestive tract hyperirritability is most important and yet naturally enough difficult to measure.¹³ Certainly there are countless instances in which the disorder is entirely psychogenic.^{14 15 16} The physiologist may object at this point and say that while the phenomenon is psychologically determined the mechanism is physiologic, and so it is. Nausea, vomiting, abdominal distress, constipation and diarrhea may be phenomena as simple, as physiologic and as psychologic as blushing of the face. The well known diarrhea of fear is an example. Usually, however, the clinical picture is much more complicated, it encompasses the numerous chronic anxieties and frustrations of life with all its difficult and irreversible personal relationships. The physician usually wisely deals with his patient on the level of the conscious only and leaves to the psychiatrist those patients in whom exploration of the vast realm of the subconscious is necessary.

The problem of etiology may be summarized by the statement that in the great majority of patients afflicted with functional disturbances of the digestive tract there is a hyperirritable nervous system, psychogenically or emotionally determined or perhaps constitutionally hyperactive and inadequate to withstand stress combined with habits deleterious to the individual such as the constant use of cathartics, enemas, tobacco, alcohol, overeating or other dietary practices not well tolerated by the patient.²⁰

TREATMENT

The therapy of functional disorders of the digestive tract may be divided into those procedures based on physiologic desiderata and those based on psychiatric or psychologic considerations. The former are rather easily defined and outlined, for they deal with diet, medication, enemas and such objective procedures, the latter are intangible and difficult to define in nonpsychiatric terms for they depend too often on the "art" of medicine, upon more or less unconscious psychotherapy upon the attitude of the physician.²¹ Arthur Hertzler²¹ one of the ablest general practitioners of the old school and a shrewd judge of human nature, wrote at length on this subject, drew many amusing caricatures, and concluded with the following direct advice: "It is misleading to speak of stomach complaints as gastric neuroses. This designation suggests that the stomach is at fault but the stomach is not at fault. It is the patient who is nervous. Forget the stomach and cause the patient to forget it." There can be little doubt that in Hertzler's heart and practice there was an abundant warmth of understanding even though he may have had little knowledge of formal psychiatry and no comprehension of modern psychoanalytic concepts. The general practitioner of today is better prepared to cope with these phases of medicine, the practitioner of tomorrow will have a great advantage over his predecessors as a result of the general increase in psychiatric teaching and training now taking place in our medical schools and the numerous excellent books on the subject.^{18, 20} The social worker is often of very real help in acquainting the physician with relevant information and in assisting the patient to gain a better understanding and in numerous ways resolve trying situations.²⁰

Diet—All food and drink is more or less stimulating or irritating to the digestive tract. Hence in acute disturbances a period of starvation is highly desirable its length depending upon the severity and duration of symptoms. The first substances to be given should be hot water, broth, barley gruel and weak tea followed by oven-toasted bread, cream of wheat, boiled milk, cooked eggs, rice, custard, jello and blanc mange (see section I of diet). As improvement occurs the diet may be increased and liberalized in accordance with the principles to be described.

In chronic disturbances the initial period of starvation is usually unnecessary and the limitation in food need not be nearly so strict. As a rule it is wise to give the patient a diet with certain specific instructions, although in some instances even this may be unnecessary

DIET

I FOODS WITH LITTLE IRRITANT AND HENCE BEST TOLERATED IN ACUTE DISTURBANCES

Water, weak tea, rice or barley gruel, meat broth, cream of wheat, oven-toasted bread, zwieback or toasted soda crackers with butter, soft cooked eggs, boiled milk, custard, plain jello

II MORE SUBSTANTIAL BUT RELATIVELY BLAND AND EASILY DIGESTIBLE FOODS

Cereals with milk or cream

Refined rice

Rice Krispies

Rice Flakes

Puffed Rice

Cornflakes

Puffed Wheat

Oatmeal (well cooked)

Macaroni

Noodles

Spaghetti

Vermicelli

Soups Consomme

Strained chicken broth

Strained vegetable soup

Strained cream of rice soup

Strained cream of potato soup

Strained cream of celery soup

Strained cream of mushroom soup

Strained vegetable soup

Cheese Cream cheese

American cheese

Swiss cheese

Cottage cheese

Edam cheese

Fish Salmon

Tuna

Whitefish

Fowl

Chicken

Turkey

Squab

Meats broiled, boiled or roasted (or baked)

Beef

Ham

Veal

Liver

Lamb

Potato baked, mashed, or au gratin

Breads White bread

Toast

Croutons

Bread sticks

Milk toast

Hot biscuits of white flour

Hot rolls

Whole wheat bread

Milk products Milk, cream, cocoa, eggnog, butter

Other beverages tea, Sanka, Postum, coffee

Desserts Vanilla custard

Caramel custard

Floating island

Rice custard

Angel food cake

Cream puffs

Eclairs

Icebox cake

Ice cream, plain

Bread pudding

Tapioca pudding

Cornstarch pudding

Spanish cream

Plain cake

Lady fingers

Sponge cake

Boston cream pie

Pies

Lemon cream

Banana cream

Coconut cream

Bavarian cream

Snow pudding

Plain jello

Cottage pudding

Peter Pan cookies

Hydrox cookies

Arrowroot cookies

Custard

Chocolate

III. COOKED VEGETABLES, MORE LAXATIVE CHIEFLY BECAUSE OF GREATER RESIDUE

A. Moderately irritating

Asparagus	Spinach	Tomatoes
String beans	Sweet potato	Beets
Carrots	Peas	

B. More irritating

Artichokes	Rutabaga	Broccoli
Parsnips	Eggplant	Navy beans
Onions	Green peppers	Lima beans
Cabbage	Turnips	Squash
Cauliflower	Kohlrabi	Corn

IV. COOKED FRUIT, MORE LAXATIVE BECAUSE OF CHEMICAL IRRITANTS

Prunes	Pears	Grapes
Peaches	Baked apple	Pineapple
Applesauce	Plums	Rhubarb
Figs	Cherries	Fruit pies
Apricots	Berries of all kinds	

V. RAW VEGETABLES, MORE LAXATIVE

Lettuce	Endive	Onions
Celery	Tomatoes	Cabbage
Watercress	Radishes	Cucumbers

VI. RAW FRUITS, MORE LAXATIVE

Banana (least laxative)	Pears
Oranges (juice, sections, whole)	Peaches
Grapefruit (juice, sections, whole)	Cherries
Apples	Grapes
Melon	Plums
Pineapple	Apricot
Berries of all kinds	Avocado Pear

VII. MISCELLANEOUS FOODS, SOME VERY LAXATIVE, SUCH AS HONEY AND BEER

Ice cream with fruit	Pickles, olives, relishes
Ice cream with nuts	Catsup
Jam, jelly, marmalade, honey	Soft drinks Coca Cola,
Syrup	gingerale, sodas, cider
Nuts	Alcoholic beverages beer
Pop corn	wine, whiskey, etc.
Candy	Buttermilk

In practice, a diet form such as the one outlined may be used. This is, as given, a full diet arranged in a manner to enable the physician to delete rather easily certain articles of food or groups of articles. Many of the more irritating foods such as the raw fruits, vegetables and miscellaneous items listed in sections V, VI and VII may be prohibited entirely. A fairly satisfactory procedure is that of permitting the patient to eat all of the items in sections I to IV inclusive except for the more irritating cooked fruits and vegetables. The amount of cooked vegetable and fruit should be stipulated as perhaps two dishes of cooked vegetable and two dishes of cooked fruit. If the distress and

In chronic disturbances the initial period of starvation is usually unnecessary and the limitation in food need not be nearly so strict. As a rule it is wise to give the patient a diet with certain specific instructions, although in some instances even this may be unnecessary.

Nuts	Alcoholic beverages beer
Pop corn	wine, whiskey etc.
Candy	Buttermilk

In practice, a diet form such as the one outlined may be used. This is as given, a full diet arranged in a manner to enable the physician to delete rather easily certain articles of food or groups of articles. Many of the more irritating foods such as the raw fruits, vegetables and miscellaneous items listed in sections V, VI and VII may be prohibited entirely. A fairly satisfactory procedure is that of permitting the patient to eat all of the items in sections I to IV inclusive except for the more irritating cooked fruits and vegetables. The amount of cooked vegetable and fruit should be stipulated as perhaps two dishes of cooked vegetable and two dishes of cooked fruit. In the distress and

intestinal hyperactivity persist, these may be reduced or eliminated, if the symptoms disappear, qualitative and quantitative additions may be made to the diet. If the stools become hard and dry the amount of laxative food eaten should be increased, spinach, lettuce, whole wheat bread, prunes and figs being especially helpful.

Rest and Exercise—In patients with a very irritable colon, rest is of great value and conversely, in patients with atonic constipation exercise is helpful. The amount of rest indicated depends upon the severity of the disturbance. When the pain is severe, complete bed rest is in order. In the average case long hours of sleep at night and perhaps a nap or rest period in the afternoon are adequate. The amount of rest as well as the amount and type of exercise to prescribe cannot be stated categorically. Both are important. The exercise should not be too strenuous and it should give pleasure. The mechanism of the health-giving effect of physical exertion and of sunlight is not well understood but it is nevertheless definite.

Antispasmodics and Sedatives—Belladonna, a time honored and valuable antispasmodic, may be given in the form of the extract, $\frac{1}{2}$ grain, or the tincture, ten to fifteen minims, three or four times daily. Phenobarbital is very helpful as a sedative and as an antispasmodic for it does inhibit intestinal activity. It may be administered as the elixir three or four times daily but preferably in tablet form, $\frac{1}{4}$ to $\frac{1}{2}$ grain three or four times daily. When insomnia exists, the phenobarbital may be used advantageously in a single dose of $1\frac{1}{2}$ grains at bedtime. Other preparations such as seconal or nembutol may be substituted if preferred or if objectionable side effects appear such as dizziness. Occasionally, for short periods, the bromides may provide more satisfactory relaxation. Numerous other sedative and antispasmodic drugs are on the market but they have not proved superior to the older and cheaper drugs mentioned. The opiates increase the muscular tonus and are not desirable.

In most instances the application of external heat in the form of an electric pad or a hot water bottle affords symptomatic relief of the distress and seems to quiet the bowel. It may be used continuously, on alternate hours, or for an hour or two after each meal, depending on the severity of the discomfort. Burns must be carefully avoided. Hot stupes are commonly employed but are usually unnecessary. A hot tub bath often accomplishes surprising relaxation.

Avoidance of Laxatives and Enemas—Laxative preparations of all kinds including mineral oil are to be avoided. They irritate the bowel, teach the patient bad habits, and are unnecessary. This is true on the whole of the relatively mild so-called bulk-producing substances, although in general these are much less irritating than the laxatives. The frequent use of large enemas of various kinds is also to be decried.

One may use small water enemas of $\frac{1}{2}$ to 1 pint to stimulate the defecation reflex in instances in which it is lacking and in which the stool tends to collect in hard masses in the rectum. The patient may need assistance in expelling such fecal impactions. At times it is necessary to break them up with the gloved finger and stimulate evacuation by means of a water enema. In such individuals the use of a retention enema consisting of three or four ounces of mineral oil or olive oil given at bedtime is helpful in softening the feces and restoring the defecatory reflex. Glycerine or soap suppositories are very effective in some patients afflicted with this condition. It is important to remember that fecal impactions usually form in the rectum not above it and that one need not worry if a few days pass without a bowel movement provided there is no accumulation of feces in the rectum. Constipation does not consist in the absence of a bowel movement for two or three or more days but in the passage of hard dry stools.

The interdiction against laxatives and enemas should not be carried to the point of prohibiting them under all conditions. There is no disease in which they are curative but they are of value in certain ways, as in the preparation of the patient for operation or for x-ray examination of the colon. Furthermore, many people for one reason or another develop the cathartic habit, experience no abdominal distress or ill effect therefrom, and should be allowed the privilege of continuing the habit even though it is unnecessary. Certain bedridden patients, if they obtain with a laxative a large daily bowel movement are happier than they are if they do not. This may be a fixation or 'preoccupation' on the part of the patient but in the absence of abdominal distress there is no objection to the habit.

Résumé—In the vast majority of patients with functional disorders of the digestive tract the physiologic program outlined above, together with the superficial psychotherapy involved in the exclusion of organic disease, the prescription of a diet together with medication and the reassurance thus given is sufficient to relieve the symptoms and restore normal gastro intestinal function. The physician should be continually on the alert, however, to detect undiagnosed organic disease and the many psychiatric disorders masquerading as functional digestive disturbances. These disorders are of all types: simple psychoneuroses in which an adequate adjustment is easily restored; complicated psychoneuroses seeming almost impossible to improve; mild or severe reactive and endogenous depressions; hysterics; migraines; schizophrenia; paranoias and all manner of combinations. For such individuals an experienced psychiatrist may prove to be of as much help in time of trouble as a surgeon is in the presence of an acute surgical emergency. However, both the surgeon and the psychiatrist should be consulted, if possible, before the emergency arises.

RENAL INSUFFICIENCY REVERSIBLE AND IRREVERSIBLE

ROBERT F. LOEB, M.D., F.A.C.P.*

A HOPELESS prognosis is generally meted out to the uremic patient because decompensated renal insufficiency characterized by progressive nitrogen retention, appears as the terminal event in three common types of kidney disorders for which there are today no known cures. These disorders are chronic glomerulonephritis, arteriolar nephrosclerosis, and chronic pyelonephritis. On the other hand, decompensated renal insufficiency may be wholly reversible. It is the purpose of this clinic to emphasize this fact and to point out that the uremic patient is always deserving of study with whatever techniques may be essential in an attempt to determine the underlying cause of his renal failure.

Once the diagnosis of renal insufficiency with nitrogen retention is established, consideration should next be given to the all-important question of whether or not the underlying cause may be alleviated. In the accompanying table is given a partial list of disorders which may lead to decompensated renal insufficiency. It is apparent that the group of disorders in which renal failure may be present is extraordinarily diverse. It embraces disturbances which may be acute or chronic. It includes pathological states in which renal failure finds its origin primarily in a decrease in renal blood flow and not in significant primary parenchymatous disease of the kidneys. It includes disease in which renal failure is at times spontaneously reversible as well as those disorders which, despite all therapy, progress to a fatal outcome. It also includes a most important group of abnormalities in which there is mechanical obstruction to urine flow.

The cause of renal insufficiency is often apparent as, for example, in patients with well documented chronic glomerulonephritis. It is equally apparent in acute nephritis with generalized edema or in various types of poisoning. There is also little question concerning the mechanisms involved in patients in whom renal insufficiency is based upon an acute decrease in kidney blood flow. However in many patients, the reason for renal insufficiency cannot be clarified on the basis of the clinical history, physical examination, or the examination of the urine alone. In these patients the possibility that uremic manifestations may arise from partial obstruction to urine flow must be borne in mind. When the

DISORDERS THAT MAY LEAD TO DECOMPENSATED RENAL INSUFFICIENCY

A Reversible Decompensated Renal Insufficiency*

I Due primarily to changes occurring in renal parenchyma

- (1) Acute glomerulonephritis
- (2) Carbon tetrachloride poisoning
- (3) Mercury poisoning
- (4) Sulfonamide nephrosis
- (5) Transfusion "nephritis"
- (6) Toxemia of pregnancy
- (7) Severe burns

II Due primarily to decrease in renal blood flow

- (1) Severe dehydration and loss of inorganic base
 - (a) Diabetic acidosis
 - (b) Severe diarrhea
 - (c) High intestinal obstruction with excessive vomiting or enterostomies
 - (d) Adrenal insufficiency
- (2) Surgical shock
- (3) Cardiac insufficiency

III Due primarily to obstruction to urine flow

- (1) Lesions of renal pelvis and ureteropelvic junction
 - (a) Urinary calculi
 - (b) Aberrant renal vessels
 - (c) Inflammatory disease with stricture formation
 - (d) Sulfonamide crystal deposits
- (2) Ureteral obstruction
 - (a) Bilateral stone
 - (b) Inflammatory disease of ureters with or without scar formation
 - (c) Sulfonamide crystals
 - (d) Pelvic tumor with compression or invasion of ureters
- (3) Obstruction near bladder outlet
 - (a) Prostatic hypertrophy or neoplasm
 - (b) Posterior urethral valve

B Irreversible Decompensated Renal Insufficiency

I Due primarily to changes occurring in renal parenchyma †

- (1) Chronic glomerulonephritis
- (2) Hypertensive vascular disease with nephrosclerosis
- (3) Chronic pyelonephritis
- (4) Polycystic disease
- (5) Amyloid disease
- (6) Bilateral renal tuberculosis

* While the outcome in this group is often favorable, it is frequently dependent upon the type of therapy employed and the time at which it is instituted

† Although renal failure in this group is essentially irreversible, patients may continue an active existence over periods of many years despite the presence of nitrogen retention (renal decompensation)

cause of renal insufficiency is not certain beyond reasonable doubt, the patient should be subjected to a series of urological studies which serve to determine whether or not some form of obstruction is present and whether or not it can be relieved. These studies should be undertaken despite the presence of advanced uremia, because it is in this group of patients that remarkable restoration of renal function may result from the relief of obstruction, even when the prognosis would appear to be hopeless. Failure to employ all the necessary diagnostic procedures will needlessly sacrifice patients. The following case history serves as an example.

A thirty-one year-old woman with advanced rheumatoid arthritis entered the hospital in diabetic acidosis. She had not previously had symptoms referable to her urinary tract. Physical examination was essentially negative except for advanced arthritic changes and for her spleen, which was thought to be palpable. In the course of treatment of her diabetic acidosis, she received between 4000 and 5000 cc of fluid daily for several days. Her diabetes was easily controlled but her urine output was small and the specific gravity was low. Albumin was absent or at times present only in faintest traces. The blood nonprotein nitrogen level on admission was 43 mg per 100 cc.

After five days the patient developed pain in her left upper quadrant. The mass previously thought to be her spleen became very tender and was then thought to be a hydronephrotic kidney. The urinary output continued to fall and after three weeks a slightly tender mass appeared in the right flank. It was at this time felt that the patient had developed bilateral hydronephrosis for some reason in response to the large amount of fluid administered in the course of treatment of her diabetic acidosis. Cystoscopic examination was impossible because of ankylosis of both hips. The patient became anuric and passed only 140 cc. of urine in the last eighteen days of life. At the time of death her blood nonprotein nitrogen was 227 mg per 100 cc. At autopsy a fairly recent bilateral hydronephrosis was found and resulted from compression of both ureters by aberrant renal vessels.

The life of this patient might have been saved by the relief of mechanical obstruction had the possible cause of her renal insufficiency been considered and had both kidneys been explored surgically despite the fact that retrograde pyelography was impossible because of ankylosed hip joints.

DIAGNOSTIC PROCEDURES

It is obviously not practical to attempt to indicate specifically the diagnostic procedures which should be employed in any given case of renal insufficiency. Of first and foremost importance naturally is a well documented *history*, complete in all details relevant to blood pressure measurements, urinary symptoms and examination of the urine in years gone by. A few generalizations may help to clarify the usefulness as well as the limitations of the various methods of study employed.

1 *Retinal Changes*—In the presence of marked arteriolar narrowing, retinal hemorrhages, exudates and papilledema uremia is usually a

ciated with irreversible renal insufficiency. In rare instances, however, this combination of disturbances may be associated with acute glomerulonephritis which may terminate favorably. On the other hand, advanced renal insufficiency may be present without demonstrable changes in the eyegrounds. This is rarely the case in glomerulonephritis, nephrosclerosis and chronic pyelonephritis, but is more frequently true in forms of renal decompensation due to congenital anomalies and obstruction to urine flow which may be relieved by surgical technics.

2 *Blood Pressure*—Advanced renal failure may be present with or without arterial hypertension. Extreme degrees of arterial hypertension tend, however, to be associated most frequently with renal insufficiency which results from incurable disease of the kidneys.

3 *Urine Examination*—It must be emphasized that the degree of *albuminuria* in no way parallels the degree or severity of renal insufficiency. In patients with mechanical obstructions to urine flow, with advanced renal decompensation, albuminuria is often absent or minimal. The *low fixation of specific gravity* is unquestionably one of the most significant characteristics of advanced renal failure. Its presence does not, however, imply that renal insufficiency is irreversible. The relief of prostatic obstruction, for example, may be followed in time by a return of the power of concentration. *Pyuria*, when found in a "clean" specimen in the presence of renal insufficiency, should be considered as adequate grounds for cystoscopy and pyelography. The presence or absence of *urinary casts* is of little importance in determining the etiology of decompensated renal insufficiency.

4 *Nitrogen Retention*—The degree of nitrogen retention is not a measure of the reversibility of renal failure. It merely serves to indicate the presence of decompensated insufficiency. Determinations repeated from time to time indicate the trend toward or away from compensation.

5 *X-ray of Kidneys*—This finds its greatest usefulness in determining the possible presence of stone or of bilateral calcification in tuberculosis. Flat plates of the urinary tract also yield useful information concerning kidney size. Enlargement is easily recognized. On the other hand, if embedded in large fat pads, contracted kidneys may cast shadows of approximately normal size. This simple x-ray procedure should be carried out in all patients with progressive renal insufficiency.

6 *Catheterization of the Urinary Bladder*—This should be done to determine the volume of residual urine in all patients in whom the basis of renal insufficiency is not wholly apparent. It is of particular importance in males in whom prostatic obstruction may be present and in children with renal insufficiency without the degree of albuminuria usually present in glomerulonephritis.

7 *Cystoscopy and Retrograde Pyelography*—The importance of these procedures in the diagnosis of renal insufficiency of obscure ori-

gin cannot be overemphasized. All patients, both children and adults, in whom the cause of renal insufficiency is not apparent, should be cystoscoped. Pyelograms should be made to determine the patency and course of the ureters, to determine the presence of hydronephrosis or non-opaque stone, to determine the relative function of both kidneys and to determine the presence and type of infection. Pyelography is also of value to determine the presence of bilateral polycystic disease as a cause of renal failure.

8 *Intravenous Pyelography*—This procedure has relatively little value in the study of decompensated renal insufficiency because of the slow rate of elimination of the dye by renal tissue with diminished function.

9 *Surgical Exploration*—In rare instances as in the case of the patient described above, exploration of both kidneys is justifiable and indicated. Exploration with decapsulation of the kidneys may possibly be justifiable in acute renal decompensation resulting from sulfonamide nephrosis and other acute anuric states associated with marked edema of renal tissue.

THE MANAGEMENT OF CHRONIC DISEASE OF THE NERVOUS SYSTEM

DONALD J SIMONS, M D *

AND

HAROLD G WOLFF, M D., F A C P †

THE MENTAL HYGIENE OF CHRONIC DISEASE

WHEN an individual is frustrated by difficulties in locomotion or in the use of his hands and yet possesses his usual intellectual faculties, the management of his attitudes is of the greatest importance. As this aspect of treatment is the least tangible and the most difficult, it is often neglected by the physician who too often considers it beyond his powers or too time-consuming. Such a physician may well ask himself if he can afford the time to practice medicine.

Physicians should beware of and watch for patients who, suddenly realizing that they are to be permanently disabled, sustain a total collapse of morale. They admit no interests, they demand help with everything, they indulge in self-pity. In these patients the problem is to prevent self-pity, to develop self-reliance, to reduce self-awareness, to avoid inertia, and to maintain interests outside himself.

Prevention of Self-Pity—These patients must be treated firmly from the inception. The physician should discuss the problems confronting the patient with the family and explain to them not only the nature and prognosis of the illness but also his plan of management. The family's help should be enlisted in controlling visitors and in advising them of the relevant parts of the situation. Some patients are quick to use physician, family and friends against one another.

The physician should also discuss the illness and the plan of management with the intelligent patient in such a way as to relieve anxiety and fear and to build up in the patient a feeling of security through confidence in his physician. During the first few weeks of illness sympathy is likely to be overdone. It is well to point out to the family that excessive sympathy engenders self-pity. Self-pity is one of the greatest evils afflicting the invalid. The physician must take pains to

From the New York Hospital and the Departments of Medicine and Psychiatry, Cornell University Medical College, New York City

* Assistant Professor of Clinical Medicine (Neurology), Cornell University Medical College, Physician to Out-patients, New York Hospital, Attending Neurologist, Midtown Hospital

† Associate Professor of Medicine (Neurology), Cornell University Medical College, Associate Attending Physician, New York Hospital, Assistant Attending Psychiatrist, Payne Whitney Psychiatric Clinic

avoid appearing unkind. He would do well to point out that he understands and shares the patient's feelings but that the frequent expression of that sympathy works against the patient's own best interests. An irritable, impatient physician may give his patients the impression that he thinks they are neurotic, malingering, or hysterical.

Development of Self Reliance—In a gentle but none-the-less certain manner it is necessary to make clear to every patient that he is expected to rely upon himself with respect to his physical comforts, his use of time, and the development of his interests and amusements. He must be "put on his own" and made responsible for his morale. The physician may point out to the patient that he should not lean too heavily upon sympathy or help.

It is often desirable to explain to the intelligent patient just what the limitations of his immediate situation are. (There is no need or excuse for detailing his ever-increasing future limitations.) One may point out that refusal to understand and accept the situation or that reactions of rage, futility and despair constitute emotional behavior designed to arouse sympathy. The patient must begin by trying to accept his handicaps with as little emotion as possible and by resolving to fend for himself to the limit of his ability.

An occasional patient will hesitate to accept his handicap thinking his disability temporary. Such a patient is avoiding the issue and has not understood his situation. He must be led to face reality and to deal with things as they are. When there is hesitation in undertaking self help, the physician must investigate its origin at once. What causes the delay—desire for sympathy? inertia? timidity? a lack of motive? shock at the realization of the handicap? a belief that his family does not appreciate his difficulty? a feeling that the objectives recommended are of little merit? At this point in the patient's relation to his illness, stagnation of his attitude may easily prove a handicap to any subsequent satisfactory adjustment. The patient must take some kind of action at once. He should be pressed to continue working at his job as long as he is employable. If unemployable, he must get out of the house daily by wheelchair if necessary, to maintain contact with friends and his former haunts. Bed rest must be avoided as long and as much as possible.

Reduction of Self Awareness—Patients with involuntary movements, abnormal postures, or masklike faces are acutely aware of their appearance. They often exaggerate in their minds the impression they think they make upon others, hence, an urge to withdraw from social contacts and to avoid friends is common. Exasperation over muscle weakness or involuntary movements causes patients to give up one activity after another before there is any need for it. In slowly advancing chronic disease the tendency to give up and withdraw may develop insidiously. Therefore, the physician must prevent any trend in this

direction A frank discussion of the desire to withdraw is sometimes indicated

A Regular Routine—Establishment of a regular routine is desirable. Fixed times for rising, for retiring, for baths, for meals, for reading, for the afternoon nap, for exercises, and for walks avoid the necessity of making decisions, diminish inertia, and serve to make the patient less aware of himself

Cultivation of Interests Outside Self—In contrast to the rather stern attitude toward the patient and his illness which has been detailed above, the physician may exert a more benign influence by calling attention to the fact that a vast amount of much-sought-after leisure time is now available for the many things which the patient has always wanted to do The patient should be induced to utilize this leisure to the fullest extent along constructive lines, for constructive efforts offer the greatest rewards in satisfaction

Museums may serve as a stimulus to drawing, painting, modeling in clay or platercine, and to the study of the cultures of other peoples and of earlier civilizations Many museums have classes which are instructive and entertaining

Where the use of the hands is impaired, a course of reading may provide useful occupation Reading can be facilitated by placing a lap-board or card table across the arms of a chair to hold the book and by using a paper weight to hold the pages down

If vision is impaired, the patient may enjoy cultivating his musical tastes in a serious manner He may further profit by listening while someone reads aloud If this is not feasible, a Talking Book Machine may be purchased from the American Foundation for the Blind, 15 West 16th Street, New York City, for \$45 00 or rented from the U S Government through any local organization aiding the blind Recordings of books of all types are available throughout the country upon application to the New York Public Library, Fifth Avenue and 42nd Street, New York City

For those whose only handicap is blindness, schools are available to teach typing and the use of the dictaphone, also canning, weaving, and playing musical instruments Many other occupations, such as masseur or newsdealer, are open to the blind

When defects confine the patient to his bed or chair, jig-saw puzzles, chess, checkers, and card games such as Russian Bank or solitaire which do not require the player to hold cards in the hand are useful pastimes

The fact of making something and possibly of selling it is a powerful builder of morale Professional occupational therapists should be obtained to teach the patient how to work with leather or metal and how to weave, model with clay, or bind books according to the patient's capacity Creative activity diminishes the feeling of hopelessness which so often plagues the chronically ill.

THE MANAGEMENT OF CHRONIC MOTOR AND SENSORY DISORDERS

Myelitis (Myelopathy)—Whether infectious, traumatic, or neoplastic, the general management of chronic myelopathy is the same. Since myelopathy is characterized by some degree of motor weakness (usually complete paralysis below the waist) and sensory impairment, almost all these patients are bedfast.

Where there is x-ray evidence of protrusion of bone fragments into the vertebral canal, operation is indicated. Intravenous hypertonic glucose and/or saturated solution of magnesium sulfate 100 cc by rectum should be given to reduce intrathecal pressure. Usually for three or four days after the injury the cord is markedly edematous, therefore, the dura should not be incised for the cord may rupture explosively.

In the case of myelopathy due to infection, the usual measures against the agent should be taken. Syphilis is a common cause of myelopathy.

For convenience in nursing, the bed may be turned so that the patient's head is at the foot end of the bed. Bed boards should be laid on the bed frame to support the mattress. A sponge rubber mattress or an air mattress should be placed upon the regular mattress and inspected twice daily to see that it maintains proper inflation. The mattress is covered with a blanket upon which the patient lies. No sheet is used. A blanket wrinkles less, is softer, and absorbs moisture better than a sheet. In the case of a fractured spine, a tightly rolled blanket secured by adhesive tape can be placed under the air mattress at the level of the fracture in order to secure the proper hyperextension. No pillow is used under the head. The position of the patient with respect to the blanket roll must be checked by the nurse every two hours, for the patient slides easily and imperceptibly on an air mattress.

In all cases the *care of the skin* is of the utmost importance. Bed sores can be prevented only by an exact routine. The patient should be turned every hour by the clock and with each turning the skin should be rubbed with alcohol and carefully and thoroughly dried. Sterile dusting powder should be applied between the toes and in any folds of skin. The patient should not lie on wrinkles in the blanket. Hyperemic areas should be painted with tincture of benzoin twice in every twenty-four hours. Munro⁵ recommends that abscesses should be tapped and drained through a needle and syringe. Incision and drainage are contraindicated. Sloughs and gangrenous tissue should not be excised but should be allowed to drop off.

A small pillow should be placed under the knees to keep them bent. Another pillow at the baseboard of the bed may be used to keep the feet in dorsiflexion. The paralyzed extremities should receive passive and, if there is any motor power whatever, active exercise at regular intervals at least three times daily for ten to twenty minutes. The

serves to maintain muscle function and to prevent stiff, painful joints when anesthesia is not complete

Formerly, when there was loss of sphincter control, patients with myelopathy have died from ascending urinary tract infection. Urinary infection can nearly always be prevented by the use of tidal drainage and irrigation as described by Munro.⁶ One of the sulfa drugs may be used to advantage if infection occurs. The patient should receive a daily soapsuds enema to prevent impaction or fecal incontinence. The occasional use of a rectal tube left in place may relieve gaseous distention of the bowel. Prostigmine methylsulfate 1 cc of 1:2000 solution may be given hypodermically every hour for three doses when abdominal distention is acute or obstinate. The blood pressure should be measured frequently during this treatment.

In the case of myelopathy following *fracture of the spine*, the patient may be gotten up in a wheelchair as soon as the fracture has healed. Functions lost through anatomic interruption of the fibers in the cord will never be regained. Functions lost through pathophysiologic interruption of nerve conduction may return gradually over a period of months. There is no way to determine which type of interruption has occurred in any given defect except by the observation of returning function.

Syringomyelia—Some patients with syringomyelia suffer from pain which may be due to the pressure of fluid within the syringomyelic cavity or the dragging of the fluid filled cord upon posterior roots. *Roentgen radiation* of the cord, 400 r units a week alternating from either side of the spine and covering a larger field than the clinical picture indicates, may help to relieve the pain. *Radium* has been used with beneficial results.

When there is evidence of a spinal fluid block and x-ray is not helpful in relieving pain, a surgical drainage of the syringomyelic cavity with rhizotomy of any distorted posterior roots is indicated. Some surgeons have advocated keeping the myelotomy incision open by inserting small slips of rubber down into the cord incision and clipping them in place with silver clips.

Myasthenia Gravis—Myasthenia gravis may be distinguished from the weakness of hyperthyroid disease by the fact that it does not respond to iodine but does respond to prostigmine. The absence of atrophy and the normal creatine metabolism separate it from muscle dystrophies. Morning fatigue and weakness—manifestations of psychoneurosis—do not affect specific muscles. Bulbar palsy gives a different history, shows atrophy of the tongue, and has a rapid downhill course.

The basis of the treatment of myasthenia gravis is *rest* and the *avoidance of physical and emotional strain*. Fatigue invariably provokes the symptoms and untoward emotion may precipitate severe muscle weakness.

Thymic tumor is found at autopsy in about 50 per cent of patients with myasthenia gravis. If suspected, operative exploration is indicated in patients who are average surgical risks.

Glycine 20 gm (4 teaspoonfuls) daily may be taken in ginger ale with benefit in mild forms of myasthenia. Ephedrine sulfate 25 mg ($\frac{3}{8}$ grain) is more effective and may be used by itself or as a supplement to glycine.

The most potent *drug* is prostigmine bromide available in 15-mg ($\frac{1}{4}$ grain) tablets and prostigmine methylsulfate available in 1-cc. ampules containing either a 1:2000 (0.5 mg) or 1:4000 (0.25 mg) aqueous solution for intramuscular use. Full function will not be restored by prostigmine and the dose should not be increased in the hope of completely restoring function.

Deep *x-ray radiation* of the thymus is recommended for patients who are not doing well or who are getting worse.

In young individuals whose symptoms are moderately severe, excision of the normal thymus may be considered. In our experience operation has benefited about half of the patients who submitted to it. Since the operative risk is great, the question of operation should be fully explained to the patient and his family. The responsibility of accepting or rejecting operation should lodge with the patient or his responsible relatives.

Headache—Headache is probably the commonest complaint in medicine. Its causes are manifold but only the two commonest varieties can be discussed.

Migraine headaches are paroxysmal throbbing mild to severe aching pains usually unilateral at the onset, located in the forehead, temple, behind the eye, or occasionally above the mastoid process, sometimes preceded by visual scotomas or scintillations and other sensory manifestations, and frequently accompanied by nausea and/or vomiting, "sickness" and chills. Occasionally diarrhea, excessive lacrimation or fever up to 39° C. (102° F) may occur. This condition commonly runs in families.

Tension headaches are steady, dull to severe aching pains in the frontal or occipital regions often described as pressure pains or a tight band around the head. They are commonly associated with tight cords in the neck and soreness in the distribution of the trapezius muscles. Though usually bilateral they may be unilateral and they may be associated with aching muscles in the jaws, shoulders or arms.

The mechanism of the migraine headache is painful distention of branches of the cranial arteries and the mechanism of the tension headache is sustained contraction of the muscles of the neck and scalp.

Emotional states, such as frustration, resentment, hostility and humiliation associated with abrupt change in the pace of living such as occurs on holidays or week-ends together with physical fatigue act

vate the migraine mechanism. Hurry, worry, anxiety and work under pressure activate the muscle tension mechanism. Tension headaches often occur in association with migraine.

The fundamental treatment of these headaches is *not* the use of drugs. Vasoconstrictors, of which ergotamine tartrate, 0.5 mg intramuscularly, is the best, and analgesics (aspirin, codeine) may be used for the symptomatic treatment of a migraine attack. Massage, the application of moist heat, or the injection of not more than 20 cc. of 1 per cent procaine into the neck muscles will relieve tension headache. The injection of procaine should not be done repeatedly. Its greatest usefulness is in interrupting prolonged attacks of pain. Before injecting procaine, one should pull back on the plunger of the syringe to make sure that the needle is not in a vein.

The treatment of the *underlying causes* for these headaches centers about evaluation and demonstration to the patient of the characteristics of his personality, its aims and its frustrations, and in examining his physical and emotional environment with a view to a better regulation of himself, his desires, his attitudes, and his activities. The physician should in the course of this review of the patient try to enable the patient to become aware of his tension as it is developing or of the onset of fatigue and to accept these phenomena as warnings of pernicious behavior.⁹ The special services of a psychiatrist will be needed for this task in some cases.

The daily or twice daily use of a "*relaxing bath*" is often helpful in obtaining muscle relaxation, rest, and the relief of feelings of pressure. Instruct the patient to fill a tub full of water the temperature of which when tested with the hand is neither hot nor cool (approximately 96° to 98° F). The eyes should be shaded from direct light. A folded towel or sponge should be used as a head or neck rest. The patient should be completely relaxed nearly flat on his back in the tub and covered as much as possible by the water for thirty minutes. This is followed by gentle drying.

Convulsive Disorders—The most important feature in the management of convulsive disorders is the determination of the cause. A seizure should be looked upon as a symptom until proved otherwise. In the newborn, congenital anomalies and birth injuries are common causes of fits. In infants with a convulsive diathesis, an acute infection may begin with seizures. Convulsive attacks occurring for the first time in an adult may be caused by syphilis, brain tumor, poisoning, or vascular disease. Consultation with a neurologist who can make a detailed study of the nervous system and who has facilities for electroencephalography and possibly pneumoencephalography is essential.

If no cause for seizures can be found upon detailed study and continuous observation, then the attacks may be considered cryptogenic convulsions of the grand mal, petit mal, automatic, or combined types.

In the treatment of fits, first place should be given to the *psychological aspects* of the problem. A basis for the management of such disorders should be laid with a review of the patient's personal history and an understanding of the social and personal problems which confront him. It is well established that emotional upsets may precipitate attacks in persons subject to seizures. Much can be done for the patient by the physician's taking interest in the patient's emotions and conflicts and by adjusting his life situation.

No patient who has fits should be permitted to drive an automobile or any other motor-driven vehicle. Bicycle riding in city traffic should also be forbidden. In the company of a responsible person swimming is permissible.

Diet may be unrestricted except in the matter of fluids. Patients whose attacks are not readily controlled by medication should restrict the total fluid intake including soup to not more than four glasses in twenty-four hours in winter or six glasses in summer. The ketogenic diet is both unpalatable and difficult to prepare, its usefulness is therefore limited.

Among the useful anticonvulsant *drugs* phenobarbital is the drug of choice. It is effective and toxic reactions (skin lesions) are extremely rare. For small children it may be given in the form of elixir of phenobarbital 1 teaspoonful (0.015 gm [$\frac{1}{4}$ grain]) once to four times daily after meals as the frequency of the attacks warrants. Adults may be started with phenobarbital tablets each 0.03 gm ($\frac{1}{2}$ grain) once to three times daily after meals according to the frequency and severity of the attacks. If this dosage is inadequate to suppress attacks, the intake may be increased up to 0.1 gm ($1\frac{1}{2}$ grains) four times a day. If a patient fears the loss of his job should he have another attack, he may be started with this latter maximum dosage which can be later gradually reduced. In no case should the drug be suddenly omitted or drastically reduced in amount, for seizures may be precipitated by this means in persons who are taking the medication for other reasons and who have never before had a fit. Patients should be given a reserve prescription and warned about the hazards of running out of medicine.

Sodium bromide 1.0 gm (15 grains) in tablet or solution form may be used by itself or in addition to phenobarbital if either alone is inadequate. Because of the frequency of bromide rash this drug is unpopular.

Should both of these drugs prove inadequate, diphenylhydantoin sodium (Dilantin Parke Davis & Co) 0.1 gm ($\frac{1}{2}$ grains) once to four times daily may be used together with phenobarbital for both together may be more effective than either one alone. This preparation is often quite effective but it is also dangerous. Untoward symptoms resulting from it are not infrequent. All patients taking this preparation should be examined and questioned at monthly intervals.

for poisoning may develop suddenly even after a year's successful use. Untoward effects are manifested by overgrowth of the gums with excessive bleeding, failing attention, memory and concentration, unsteady, staggering gait, awkwardness and tremor of the hands, and purpura. Intellectual deterioration may result if the drug is not withdrawn. Death has been reported as a result of purpura. Fortunately, the minor symptoms clear up readily upon withdrawal of the drug.

Narcolepsy, or uncontrollable sleepiness, may be treated by amphetamine sulfate (benzedrine) which is available in 5-mg ($\frac{1}{12}$ grain) and 10-mg ($\frac{1}{6}$ grain) tablets. It is seldom necessary to give more than 20 mg ($\frac{1}{3}$ grain) in one dose. The frequency of administration will vary with the patient. Constipation, loss of appetite, and sweating are some of the unpleasant side reactions of this drug. Ephedrine sulfate 25 mg ($\frac{3}{8}$ grain) has also been used with good results but it is less effective than amphetamine.

Catalepsy, or sudden muscle weakness associated with emotion, is not known to respond to any type of medication. The possibilities of psychotherapy have not been adequately explored.

Herpes Zoster (Shingles)—Although herpes is not a chronic disease in young persons, it may become a chronic painful state in older persons. Treatment should begin with the skin lesions.

For the herpetic lesions, zinc stearate powder and a bandage to prevent rubbing of the clothes over the hyperesthetic skin, or, if the lesions are painful, 1 per cent cocaine ointment with lanolin may be used. Collodion may be used to protect lesions on the face. Where lesions threaten the eyeball, the lid should be kept closed and the eye covered. The pupil should be kept dilated with sterile 1 per cent atropine sulfate solution, one or two drops daily. The possibility of glaucoma secondary to atropine must be considered and, should it develop, suitable treatment must be instigated.

For the pain, acetylsalicylic acid 0.3 to 0.6 gm (5 to 10 grains) may be used every two to three hours. In this condition there is danger of morphine addiction developing because of the prolonged period of pain, therefore, morphine should never be used. Pain is likely to be troublesome in direct proportion to the age of the patient. In the youthful it is seldom a problem, in the aged it may persist for months. In many cases the fear that the pain will never go is more troublesome than the actual pain. It is well to tell the patient at each visit that his pain *will* disappear in the course of time. The pain seldom lasts more than twelve to eighteen months in any event. X-ray therapy in small doses directed against the diseased dorsal spinal ganglia is said to be helpful in some cases.

For severe postherpetic pain, section of the posterior roots and chordotomy have been tried, but neither offers any certainty of relief, the latter is the more likely to prove helpful but its danger is great!

Parkinsonism (Paralysis Agitans)—In parkinsonism the attentive, never-despering attitude of the physician is especially of great importance. The remarks made in discussing the mental hygiene of chronic disease of the nervous system apply here particularly.

Passive manipulation of the extremities with stretching of the muscles morning and evening may relieve some pain, prevent contractures, and remind the patient that something is being done to help him. Patients confined to a bed and chair existence may appreciate the chance every hour or so to walk ten to twenty feet with the help of one or two persons. This is to be urged for its psychological more than for its physical value. When tremor affects the feet, calluses often form where the foot rubs the shoe, and other lesions may appear where one toe rubs against another. Lamb's wool, obtainable at most drug stores, keeps the skin dry and rubbing toes separated. It is superior to cotton wool. The periodic attention of a chiropodist may be desirable. Patients who spend most of the time sitting down should sit for at least twenty minutes three times daily with their feet elevated above their knees to avoid edema of the feet. Where skin lesions occur this is essential.

Once such a patient starts taking medicine it is difficult to wean him from it. Since the course of this illness may extend over many years, it is therefore wise, especially in patients under fifty years of age, to withhold drugs as long as possible. The young should use drugs only on special occasions and for special needs. Some patients may have considerable tremor and yet not be troubled by it; these should not take drugs. Others may have a moderate tremor which interferes with work or annoys when they are in company; these may take medicine as needed to meet a special occasion.

Those who have marked and troublesome *rigidity* will benefit by the following prescription:

R: Scopolamine hydrobromide tablets each 0.3 mg.

Label: One tablet three times daily.

Scopolamine hydrobromide is also available in 0.6 mg. tablets. Tremor is not influenced by drugs as much as is rigidity. It is often best to space the dosage by taking one tablet on rising, one on retiring to help in getting to sleep, and one midway between these times. Elderly patients frequently awake in the early hours of the morning and cannot get to sleep again. A tablet and a glass of water placed by the bedside at retiring and taken upon early awakening usually permit sleeping three hours longer. A maximum dosage may be six 0.6 mg. tablets daily. Dark glasses may control any discomfort from pupillary dilation when outdoors in bright summer sun or sun on snow. Dryness of the mouth may be combated by chewing gum or by using lemon drop candy.

Another drug useful in treatment is prescribed as follows:

R̄ Tincture of stramonium

240 cc

Label Fifteen drops three times daily in water after meals

The dosage may be increased up to 60 drops three times daily. Since this preparation may lose potency on standing, patients should not use material which has been standing indefinitely in their medicine cabinets. It is sometimes desirable to give scopolamine for three months followed by tincture of stramonium for one month in alternation.

While both of these drugs may cause some dryness of the mouth, atropine is more effective where *drooling* is the major complaint. It may be given in tablet form, but the dose is more easily varied when the solution is prescribed.

R̄ Atropine sulfate (0.5 per cent solution)

30 cc

Label Three drops three times daily after meals. Increase dose by 1 drop every third day up to not more than 20 drops per dose, then gradually reduce dose until adequate maintenance dose is found.

Pain due to muscle rigidity can be diminished by quinine sulfate pills* in doses up to 0.3 gm (5 grains) three times daily.

Some patients are able to manage *festination* by carrying a cane in front of them as impediment.

Weakness is the most troublesome of all complaints and the least amenable to treatment. Amphetamine sulfate (benzedrine) in 10-mg tablets on arising and again not later than 4 P.M. may be of some benefit.

Phenobarbital increases the weakness in advanced cases to a distressing degree and should be avoided.

Patients who are bothered by *weakness* or who are given to *depressed spirits* may be helped by 2.5 to 5 mg of dextro-amphetamine sulfate (Dexedrine sulfate, Smith, Kline & French) after breakfast.

The use of 30 to 45 cc of sherry or vermouth or 20 to 30 cc of whiskey served, according to the patient's taste, once or twice daily, is often of great service particularly in the most handicapped patients, for it dulls the patient's awareness of his difficulties. Since some persons react to alcohol with depression, irritability, or some other undesirable response, judgment should be exercised in prescribing alcohol.

Tabes Dorsalis—The manifold symptoms of tabes dorsalis are best managed by the "minimal prescribed routine therapy" described by the Cooperative Clinic Group.⁷ This consists in twenty arsenical injections given in courses of six or eight injections in conjunction, either continuously or intermittently, with fifteen injections of bismuth or thirty injections of mercury succinimide. " if during the first year of treatment of tabes dorsalis, or after twenty injections of arsphenamine and heavy metal, the spinal fluid is still positive, supplemental treat-

* Quinine is not obtainable for this purpose during the war.

ments should be employed" Supplemental treatments are a course of twelve to fourteen fever paroxysms, and/or not less than thirty injections of tryparsamide

Physicians should take note of the fact that in a previously untreated case a few injections may activate the luetic process and interruption of treatment at this stage sometimes proves disastrous. Patients should be warned that once treatment is begun it must be continued for at least one year and preferably for two years.

During the course of this routine treatment, some symptoms may require special attention. Patients troubled by *ataxic gait* should practice Frenkel's walking exercises for at least fifteen minutes at regular periods every day. Three times daily is an absolute minimum. Hourly is not too often. Their purpose is to coordinate vision with foot movement. To practice these exercises the patient should learn to stand upright with support. This is the first step in the process of regaining confidence. Subsequently with the support of one or two persons he should learn to walk placing his feet on bits of paper which have been laid on the floor in a straight course in the footsteps of a person walking normally. Sometimes a rug design instead of papers can be utilized for this purpose. Finally, the patient should walk the mapped course unaided. A will to learn to walk and patient practice are necessary to obtain results. Unless absolutely necessary, a patient with *tubes dorsalis* should not be allowed to remain in bed except when sleeping because the proprioceptive functions of the spinal cord may deteriorate rapidly from disuse.

Attacks of *lightning pains* in the legs are best treated by aspirin, codeine and whiskey. Supervision of this treatment by the physician or by a responsible relative is advisable, for patients are often led to excessive dosage. Thiamine chloride in large doses intramuscularly has not been proved to be useful.

In severe attacks of *gastric crises* it is advisable to put the patient to sleep with an intramuscular injection of scopolamine hydrobromide 0.6 mg ($\frac{1}{100}$ grain) and morphine sulfate 15 mg ($\frac{1}{4}$ grain). When the patient is deeply asleep he should be given slowly a phlebotomy or hypodermoclysis of 1 liter of isotonic saline and 5 per cent glucose. This should be administered whether or not there has been vomiting because in any severe attack of pain the patient loses a great deal of fluid and chloride through perspiration and heavy breathing. Should the patient when awakening appear to be still in pain he should be induced to void. If the patient is unable to take medicine by mouth a solution of 0.16 to 0.6 gm ($2\frac{1}{2}$ to 10 grains) of sodium phenobarbital in 10 cc of sterile distilled water intravenously at a rate not exceeding 1 cc per minute should be given until the patient is again asleep. To exceed this rate of injection is to court disaster in the form of cessation of respiration.

Frequently crises will terminate with a single narcosis. Occasionally severe attacks will last several days. In this event, the patient may be kept narcotized by repeated cautious injections of sodium phenobarbital. He should be allowed to awaken enough to void, but it is well to give nothing by mouth unless it be sodium phenobarbital. Fluids and chlorides must be maintained by clyses.⁸ Since these patients readily become addicts, morphine should be avoided.

If crises are severe and frequent, a bilateral high cervical chordotomy must be undertaken by a competent neurosurgeon in spite of its risk.

Optic atrophy is one of the most difficult manifestations of tabes to treat successfully. It rarely responds to any form of chemotherapy.⁴ When optic atrophy or visual field defects are found in their early stages, the patient should be given fever therapy at once. Malarial therapy—ten to twelve paroxysms—is preferable to artificial fever or typhoid inoculations. If fever therapy has been used and optic atrophy progresses, then a craniotomy for exploration of the optic chiasm is warranted. Frequently a thickened arachnoid membrane will be found compressing the chiasm. These membranes should be dissected and removed.²

For the atonic *tabetic bladder*, Langworthy³ has found that acetyl- β -methylcholine chloride (Mecholyl, Merck) 0.2 to 0.5 mg (3 to 7½ grains) is an effective drug in improving the contractile power of the bladder muscle and in decreasing the amount of residual urine “practically to zero.” Thus drug is contraindicated in asthma, it should be given cautiously to elderly patients. Should residual urine become a problem beyond the power of mecholyl, the use of a sulfa drug and/or daily catheterization may become necessary to control cystitis. Since the loss of bladder sensation is the primary difficulty in the tabetic bladder, patients must be taught to void at regular intervals to prevent stretching of the bladder muscle. Splinting of the abdominal wall with the hand may prevent kinking of the urethra, and manual pressure against the bladder may aid in micturition.

Multiple Sclerosis—Some of the symptoms of multiple sclerosis can be helped by drugs. Urinary urgency and frequency may respond to ephedrine sulfate 0.025 to 0.2 gm ($\frac{3}{8}$ to 3 grains). Spasticity is often benefited by quinine sulfate 0.3 gm (5 grains), three times a day. When the patient is depressed in spirits, dextro-amphetamine sulfate (Dexedrine sulfate, Smith, Kline & French) 2.5 to 5 mg after breakfast may greatly improve his sense of well-being.

Although multiple sclerosis may be due to some type of deficiency, at the present time there is no indication for specific vitamin therapy.

Subacute Combined System Disease (Pernicious Anemia)—In treating macrocytic hyperchromic anemia accompanied by disease of the nervous system, many physicians are satisfied to administer only sufficient amounts of liver extract to maintain the red blood cell count at five

million. This treatment may not be adequate to prevent degeneration of nerve tissue.

Presumptive evidence of the type of damage to the nervous system commonly found with macrocytic hyperchromic anemia is the complaint of numbness or prickling and tingling in the finger tips or toes. Less commonly, a stiff, awkward gait is noted. Examination of such patients may reveal diminished ability to perceive the vibrations of a tuning fork placed on the distal end of the radius or tibia. A patient may also be unable to tell whether he has been touched by one point or by two when the examiner touches the patient's unseen palm with divider points 2 cm. apart. The perception of passive movement and of the direction of movement when the big toe or a finger is moved by an examiner may be diminished.

When these symptoms and signs begin or progress during treatment, it is evident that the patient is not receiving adequate amounts of the essential substance or substances. Treatment is best carried out by intramuscular injection of the less purified and less concentrated preparations of liver extract. The volume and frequency of injection will depend upon the results obtained, and may considerably exceed the average daily dose of liver of 1 USP unit intramuscularly. No disturbances follow excess in dosage. The adequacy of treatment can be determined only by repeated neurological examinations and the patient's freedom from complaints referable to disease of the nervous system.

Nouritis (Neuropathy)—Neuritis is commonly a prolonged and often a painful illness. Bed rest is essential. A search for the cause among toxic, traumatic and infectious agents, and nutritional deficiencies is indicated. Well-padded cock-up splints for the wrists and right angled splints or other devices for the feet are necessary to prevent contractures. The skin requires special attention as detailed in the discussion of Myelopathy on page 437. A sponge rubber or an air mattress may be required if bed sores are imminent. When there is much pain, a cradle should be placed over the legs to support the weight of the bed clothes. In any case, the bedclothes should not be pulled tight over the feet.

Within the limits of tolerance, passive and active exercises and massage should be carried out regularly to keep the muscles and joints limber. Analgesics except morphine and sedatives may be used as needed. Except in nutritional deficiencies where treatment with all the vitamins is required, there is no experimental basis for administering vitamins in the treatment of neuropathy. During the painful stage of the disease dry heat in the form of infra red lamp, warm packs or electric pads, is helpful. Great care must be used in applying any form of heat for where there is sensory loss, the tissue is easily burned.

Massage and active exercise, in a pool when available, should be used regularly after pain has subsided

Cerebral Palsies of Children—These conditions fall into two groups *cerebral diplegia*, which is a congenital developmental defect, and other motor defects resulting from *intracranial hemorrhage due to birth trauma*. The latter conditions are often manifested at birth by respiratory difficulties and later by unsatisfactory feeding. Subsequently, unilateral motor weakness, rigidity, or adventitious movements may be observed. In all infants who have a history of poor nursing followed by some form of motor defect, the spinal fluid should be examined for red cells, xanthochromia, and for its protein content. Pneumoencephalograms should also be made to determine the size, shape and position of the cerebral ventricles and the presence of normal cortical markings. By this means subdural hematoma or hydroma may be diagnosed.

In congenital cerebral diplegic patients, little can be done until the patient reaches an age where he can understand instructions and cooperate in training exercises. In children of low intelligence, the results of any type of training are likely to be so poor as to make training worthless. For spastic children able to cooperate, a graded program of active exercises training motor coordination should be instituted. Rhythmic passive exercises should be carried out by a therapist experienced in this type of work. Routine passive exercises alone are not satisfactory since they exercise all muscles without coincidental instruction of the patient in the voluntary relaxation of antagonist muscles. For older children and adults who are troubled with incoordination of movement, stringing large beads on heavy string and practice with a typewriter may help to train finger dexterity. Visual training aimed at focusing the gaze on his own thumb during hand movements or upon the lips of the person to whom he is speaking correlates visual and motor activity and reduces adventitious movement. The use of a microphone and loudspeaker is helpful in speech training.

The reduction of light stimuli by wearing dark glasses and of sound stimuli by using earplugs reduces the quantity and the intensity of involuntary movements. Eating may be facilitated by serving food in a circular dish with curled in edges.

For adults the use of a cocktail before dinner will materially aid in relaxing the muscles during eating. Some adults find a cocktail of great help in walking on icy sidewalks.

Since fear, anxiety and self-consciousness are important factors influencing spasticity, incoordination and athetosis, the training and control of emotional factors is important.

Children are helped by separation from normal children so that their handicap is less obvious to them. Education and treatment in classes with children who have similar handicaps are often of great psychological advantage.

These patients require the help of specially trained teachers and therapists. Enthusiastic or inspired teachers are of great therapeutic advantage.¹

Spasmodic Torticollis—Spasmodic torticollis is a periodic, nearly constant, involuntary turning of the chin and tipping of the ear toward the shoulder. It is usually psychogenic in origin. It should be differentiated from similar conditions in which spasmodic slow contractions of muscles occur elsewhere in the body, for such patients are considered to have disease of the basal ganglia.

The primary concern in treating spasmodic torticollis is to discover and remedy the psychological causes leading to this abnormal reaction. Investigation may be carried out along the lines suggested in the treatment of Headaches (see page 440).

Symptomatic treatment consists in teaching the patient to recognize the feel of muscle contraction and to relax consciously the muscles involuntarily contracted. Quinine sulfate 0.13–0.3 gm (2 to 5 grains) may aid in relaxing. Heat applied to the neck muscles and deep massage may be of temporary benefit. Relaxing baths (see page 440) may also be of use in getting general muscle relaxation.

Amyotrophic Lateral Sclerosis and Progressive Spinal Muscular Atrophy (Chronic Poliomyelitis)—Both of these diseases are manifested by slowly progressive degenerative disease of the anterior horn cells of the spinal cord and characterized by weakness, atrophy and fasciculations. The former also shows evidence of widespread cortical ganglion cell degeneration and corticospinal tract disease characterized by increased tendon jerks and pathological plantar responses. The latter shows diminished or absent reflexes.

As no specific treatment is known for either of these diseases, care of the patient must consist in detailed attention to his mental hygiene.

Excessive exertion and fatigue and exposure to inclement weather, the extremes of temperature, and to persons suffering from any type of infection of the respiratory tract should be avoided. Stimulants are well avoided, but 45 cc of sherry or vermouth or 20 to 30 cc. of whiskey twice daily for the patient whose disease is advanced may help to diminish painful awareness of the condition. The claims advanced for the beneficial results of alpha tocopherol and other forms of vitamin therapy have not been substantiated.

Apoplexy—The term "apoplexy" applies to cerebral hemorrhage, thrombosis and embolism. The treatment of the patient who survives the acute phase of a vascular accident is essentially the same regardless of the type of accident, for the disability results from the necrosis of brain tissue secondary to loss of the blood supply. Hemiplegia with or without language defect is the common result of apoplexy.

Acute Period—In the acute period the patient should be kept in bed. The bed must be kept free from crumbs and wrinkles, for these may

damage the skin. The bed must be kept dry. This can be facilitated in the case of the incontinent patient by laying newspaper interlaid with oakum or other absorbent material under the patient's hips. It is well to have the patient sit up in bed with the sound foot braced against a bed roll or some other soft but firm support in order to prevent the patient from sliding down in bed, thus hampering respiration. The paralyzed foot should be kept in a well-padded removable cock-up splint with the knee slightly flexed over a small pillow. A cradle should support the bedclothes over the foot. The shoulder girdle should not be elevated. The upper arm should be abducted about 75 degrees. The forearm, also supported by a padded cock-up splint, may be placed on a pillow with the wrist considerably higher than the elbow. The patient's position should be changed every two hours by lifting—not dragging or pushing—the patient. Sometimes the patient can shift himself by means of a rope suspended from a frame above the bed.

It will facilitate the use of a bedpan if the surface which comes in contact with the skin is well powdered. The bedpan is most easily utilized by rolling the patient onto his side, placing the bedpan in position, and then rolling the patient back onto it.

It is inadvisable to use strong cathartics or mineral oil, for hemiplegic patients often have poor sphincter control and they may suffer considerable humiliation from soiling themselves.

Fecal impactions may be managed by seating the patient upon a commode chair. The patient should bend forward acutely against a sturdy chair. A slow-flowing enema is then administered through a 2-inch nozzle. Manipulation of the nozzle is often sufficient to break up and dislodge the impaction. Occasionally manual extraction is necessary. A teaspoonful of lysol in the bottom of the commode pan will counteract offensive odors.

Light superficial massage and deep kneading massage are both indicated. Passive movements of the paralyzed joints must be executed whenever the patient is moved and at least every three hours during the day in order to prevent pain in the joints and muscles. Active movement, at first in a horizontal plane and later against gravity and increasing resistance, must be persistently urged from the start before spasticity appears. The patient should be given a rubber ball to squeeze and roll in his fingers. Few hemiplegic patients ever recover completely and the family may be so informed early in the illness, but recovery may be aided by persisting in muscle training.

Subsequent Management—After the acute period, the patient should be taken out of bed as soon as possible for periods of increasing length each day. Relatives and attendants should be instructed on how to help a hemiplegic patient out of a chair. Always pull on the hemiplegic side. Place the right foot against the patient's right foot, if that be the hemiplegic side, and rest the right knee against the patient's right knee. With

the right hand grasp the patient's right upper arm from the inside and the back and pull steadily

Walking should be encouraged either with a walking frame the support of two persons, crutches, a cane, or a brace to prevent toe drop

The physician should warn every attendant concerning the use of hot water bottles on the paralyzed and often hypesthetic side of the body Before applying any warming device to the skin of a patient, the attendant should first apply it to his own face for fifteen seconds to test its temperature

The treatment of *aphasia* requires much patience and devotion and is not always rewarding Treatment may be started by showing the patient a single object or picture of an object and simultaneously naming it verbally and graphically This is repeated indefinitely with the same and with different objects until new associations are made The process is much the same as in teaching a small child but progress may not be so rapid

Hereditary Diseases—There remains to be mentioned a group of rare diseases which are usually hereditary and familial in incidence They have nothing in common Friedreich's ataxia Marie's hereditary cerebellar ataxia, hepatolenticular degeneration (Wilson's disease) Huntington's chorea, the myelopathies, and amyotrophies make up most of this group

Since no treatment of any value is known for any of these diseases beyond occasional benefit from glycine in muscle dystrophies and quinine in myotonia, attention must be given to the patient's mental hygiene These conditions usually progress inexorably

THE NEUROSES RELATED TO THE MANIC-DEPRESSIVE CONSTITUTION

FOSTER KENNEDY, M D , F.R S (Edin)*

At the outset of discussion one must define one's terms, the title of this chapter, "The Neuroses Related to the Manic-Depressive Constitution," must bring to mind almost as many different images as there may be readers

And the matter of the significance and emotional value of "words" will need consideration before the writing has ended, for it is certain that men do not live by bread alone, but mainly by catchwords What we *call* a thing becomes often in our conscious mind the thing itself, and the "word" can cease being what it truly is, a tool or a symbol of a thought, and grow into a god, or dwindle into a mere term of abuse

WHAT IS A HUMAN BEING?

In the consideration of the disordered thinking or disordered acting in the neurotic, we have to consider first, and to some purpose, what we imagine a human being to be is he Soul-Body-Mind? is he Body-Mind? is he a Behavioristic Body?

Is He a Soul-Body-Mind?—This is mainly a theological concept, a trinitarian formula lacking physiology, but knowing well Man's dynamic drive The psychoanalysts have taken this formula of Soul-Body-Mind over, in a style curiously debased They have replaced Hope by Lust, the Soul by Libido, and Intellect by the so-called "dominant unconscious", all in the spirit of surrealism, fantastic and rigid Uneducated by their betters and forebears, they would make, scholastically, without however the discipline of the scholastic, a brave new world out of mud pies

Psychoanalysis has been the current style by which this great trinitarian idea has been presented to us But its theories are verbal, its "science" largely dogmatic assertions unsupported by anthropological research or by masters of education, and as Freud confessed in his last lectures, it has no true therapeutic value

One might pause a moment here to regard an identical movement which ran rampant through half of the last century Most of us think Phrenology so absurd as to be totally negligible, yet it furnished for more than two generations subject for debate in newspaper, lecture-room and theater Even men like Emerson and Oliver Wendell Holmes perforce had to consider it and refer to it in the Sixties It swam in a

* Professor of Neurology, Cornell University Medical College, Director, Neurological Department, Bellevue Hospital, New York City

sea of new words for old faculties "philoprogenitiveness" has survived through its comicality, its vogue was lifted and sustained by its claim "to tell your fortune,—and the kind of thing you are,—and the most learned physicians were Chairmen of the Phrenological Societies, of which the Transactions can today be read by the curious in *The Lancet*" of, say, 1830. This pseudo-science, this strumpet among the learned, served a good purpose, like many a strumpet. It was the gilded coach which carried Gall's great idea of cerebral localization of function along the corridors of the nineteenth century, that it might become known in the Seventies to men of the caliber of Hughlings Jackson, Hitzig, Munk and Ferrier. They, throwing away its nonsense laid truly, by dint of Gall's inspiration, the foundations of our modern knowledge of the physiology of the brain.

The solid contribution of Freud, when dug out of its clay, will prove probably as important as did that of Gall. For each individual, as he grows from the embryo to the adult, is a little cycle of the race. We have long known that from the egg to death we pass through stages in our body at least similar to those through which humanity has passed before. Freud has made it clear that in our emotions, in our urgings, in the preponderance of this feeling or instinct over that, at different periods of our lives, we have a like evolution, and—if we live into senility—devolution, of personality. He has shown the child as indeed no angel, but rather, at the age of five a polytheistic savage, having for his authority, and, too, his private pleasure, a genius loci in every tree and star, and at ten as a kind of Nazi who would naturally be characterized by restricted imagination, hypertrophied tribal emotions, and truculence towards other tribes, he would be, and is regimented in ritual, totally intolerant, and—to offset his annoying sense of inadequacy—brutally contemptuous towards all those he thinks weaker than himself.

Freud has insisted that the child's sexual instincts emerge by gradual progression from an emotional preoccupation with one orifice of its body to an emotional preoccupation with another. However, Freud himself doubts the therapeutic value of this contribution to our knowledge of ourselves. But at least his teaching has made clear how our instincts have developed within the microcosm of each man's body. He has taught us, how—if inherited endowment be lacking by which to attain maturity—a man, or masses of men may stick at the different instinctual levels. However, as regards some of Freud's other conclusions, I feel that while, bodily, we have still vestigial remnants of our past, like gill slits and emotionally, others like sexual reversions, it is absurd to attempt to estimate the total adult body in terms of gill slits, or the total adult personality in terms of an uncovered sexual reversion.

Freud's work has served, then, to formulate what one might call

the phylogeny of personality and to make clear the stratification in growth of motivated desire, it has diagrammed, perhaps by oversimplification, how one emotion forms the basal matrix in the growing organism for the next emotion to be developed. It has thus unified our notions of character formation by making them analogous to the idea of anatomical recapitulation in each human organism, of the various physical stages through which humanity has passed, analogous also to the Jacksonian physiological demonstration of the nervous hierarchy, through which we see that patterns of ancient reflex behavior persist latently under the command of the last appointed controller—only to come out into the open when that control has weakened.

However, one must notice that the anatomist, appreciating the excellence of the persisting mechanisms in us of our early ancestors, appraises the whole evolved organism as more valid than are the traces of the primitive, and the Jacksonian neurologist regards cortical brain control more highly in a general way than the spinal ejaculatory reflex. Only the Freudian "psychoanalyst" reduces through a kitchen rebellion the total organism to its lowest and commonest denominator and would seek to explain its thoughts and behavior in terms, as I have just said, of its gill-slits and equally primitive sexual trends.

One sometimes wonders how the psychoanalysts justify the existence of a conscious mind at all! Possibly it is a contraption to be a psychoanalyst with!

Is He a Behavioristic Body?—This idea of man is not much more satisfactory than the one discussed. The Behavioristic School, deserted before its adolescence by its semi-parent, and chief sponsor, has shown less survival value than has Freudian dogma. Perhaps because it aspires less than Freud to tell, like palmistry, self-conscious little people more about themselves. It denies the substance of heredity and asserts roundly that "training" can make figs of thistles, and a silk purse from a sow's ear.

Once I heard the Half-Father of Behaviorism passionately deny the influence of heredity in human behavior and human structure. He said roundly and loudly to a great audience that "so far was he from believing in heredity, he was not prepared to admit, that if a human ovum and a spermatozoon were to unite outside the human uterus, the resulting organism would necessarily possess two eyes, a nose and a mouth." After ten seconds of stunned silence in the audience, a modest little man rose to assure the explodant that he "truly could have no idea the kind of pure town he was visiting, here in New York. He would assure him that if an ovum and a spermatozoon were even to *attempt* to unite on Broadway, they'd both be arrested by the police."

Or Is He a Body-Mind?—There remains Body-Mind—a dualism also of ecclesiastical origin. We know now, in the light of the New Physics, that matter, mind and structure are all the same thing—geometric pat-

terns of energy molecules, that we ourselves are, if you will, electrical aggregations of exquisite complexity and that our protoplasm is identical with our aim and purpose

But our *humanness* lies in that very complexity. By this not only can we temporarily capture energy for our use, but, by the *distilling* mechanism of our nervous system, we can transmute such primitive energy to conscious aspirations, abstract thought, and even into compassion for those about us. And our ability to do this well lies largely in the quality of brain and body which we have each been given.

WHO ARE THE NEUROTICS?

Time and Disease may each so injure our instrument of refining and distillation that the end product may be murky, uncertain and unhappy—and of these are the neurotics of whom we would speak here.

And we speak here as in a clinic, not expecting surely to reach conclusions on Human Reality in an hour and halt, so of what shall we speak? First, that "a neurotic," to quote from my first sentence, is not a term of abuse, that he is as real a thing as you or me. We might all properly say "And there, but for the Grace of God goes myself."

The jejune words "functional" and "organic" which in most speakers' minds mean "imaginary—yellow to be cuffed, and 'real—red blooded, to be cured" lame our thinking as did all the dualistic vocabulary of the Churches since the debate of Origen and Celsus. These two words, convenient as they are, obscure the question. One, "organic," refers to the "pathology of fiber" and the limitations of the microscope, the other, "functional," adumbrates the pathology of *forces*—which is the pathology of the future we, having been allowed to *see* wonderfully, have become blinded for all that cannot be seen. Further, to describe either, the patient must use words—and often these are employed not to explain, but to explain away lower happenings.

They Think, Feel and Act Unsurely—One must stress again the truly immaterial nature of man. Body-Mind is organized energy, each man organized by his inheritance into a frame of certain dimensions. Possessing, however, at the same time, certain growth possibilities, if exposed to environmental forces of culture, these can lead out of him by education all that he has. But no education can put *in* more than the educated possesses in ability to take in or to put *out*.

So the neurotic can, for many reasons, think unsurely, feel unsurely and act unsurely—and in moments of weakness nearly all of us can do these things.

Our individual complaints are vocalized according to the scope of our intellect, the range of our vocabulary, the inherited sensibility of our skin reactions and according to the innate or educated individual fortitude to which each of us has aspired and achieved.

Here, I'd ask each member of this clinic to spend one whole day

reading quickly—it is needless for our purpose to do it slowly—a number of psychiatric books. There you'll find, for sure, uncertainty, evasion, verbalism, words replacing things and often ideas, jargon and jargonese, put in, not as old words re-used, but as new words made up. These it would seem are meant to explain better, old things, old things, no one of which whole books could explain,—like "Censor" by which to replace "Conscience," like "Transference" to replace "Salvation," like all "Aspirations" abolished by "Libido." One gets lost in these weaving drifts of language which so obscure the outlines of the land one would see—and one suspects such drifting clouds may be smoke screens to hide the camouflage artist who puts them up.

And, having spent our twelve hours on this task, we return now to our pattern of thinking, feeling, acting—unsurely.

These three, thinking, feeling and acting, are, for everyday use, the total man—containing in "acting" the resultant also of the "organic" "unconscious," comprising those vast forces that determine, by no will of ours, that we should, for instance, breathe 18 to the minute, have our heart beat 72 times in the same space, keep our temperature steady in an arbitrary fashion despite surroundings and, strangest of all, lie unconscious for the hours of darkness while the earth turns round and about all of that we lack any personal experience or knowledge.

For, and few think of this, we are the target and the object of forces, from inside ourselves and from without us, of which we have no conscious awareness, these build us, undermine us, deflect us, direct us, largely by as much as we have been equipped to accept, to resist, to rule the forces impinging on us and to determine direction and result in our thought and action.

Obsessional Thinking—Please remember that no man in the world knows what is "sleep." I mean, we can describe sleep, we can discuss blood pressure, pulse rate, water balance and metabolism in sleep, but no one can say how the condition of sleep is brought about, or what it is.

With such a huge gap in our facts—and we spend a third of our lives asleep—why should we expect to know precisely the reason why a few are obsessed by fear of dying, or by distress against uncleanness, by a persecution of jealousy, by a hatred of a friend with child, or by the fear of loss of fortune in a banker lest he may have put his name to a bit of paper he sees fluttering in the street. Why should we know the exact mechanism of the persistence through adult life of the emotions of the—at that time quite normal—"magical" culture of the six-year old who must touch every third bar of a railing, who must jump over pavement cracks, the child who at the same time is a superstitious poet and a witch doctor with obsessions? The six-year old who, by the imposition of his age is, just by his nature then, a Red Indian in culture and belief.

Yes, we do have notions and ideas by which we may—not explain—but deal with these things, but to describe events is not to explain them. I remember in 1910, Dr. August Hoch showing me in Manhattan State Hospital a woman whose right hand was paralyzed in both motor and sensory “hysterical” fashion. Dr. Hoch told me with satisfaction and almost triumph, “But of course, she is distressed because of masturbation.” I could not but reply, “Surely that’s no true answer. She has only fulfilled the crude Bible command ‘if thy right hand offend thee, cut it off.’ But why had she, so imperatively to do so? Millions of women do happily what she has disapproved of doing, and make themselves steadier thereby. Why should she have to do in expiation what most of her sisters did not?” It is not enough only to *describe* the symptom, except for temporary labeling. We must ask ourselves why did *that* woman, and not the millions of other women have to substitute the “hand amputation” for the ‘hand action’ which had been unacceptable to her. We may not get the right answer. If however we do not ask ourselves such a question—or, having asked it, give ourselves only a glib reply, we then have ceased to uphold science. By that we satisfy ourselves with ourselves (and only quarter satisfied and sleeping poorly!) or we revolt against such untruthfulness, become protestant in deed and word, and, knowing no answer, continue anxiously to seek one.

Thought certainly came before speech—look at any baby if you have not believed this. It is therefore mere self protection to make wordy speech on our part take the place of thought! And how difficult for the patient to put into truly descriptive words errors in the autonomic organic unconscious.

Manic-Depressive Equivalents—The patient’s descriptions may *not* be as an image seen in a mirror, his description in words may attempt to explain away, rather than to explain. This factor doubtless enters into the manufacture of what I have called “manic depressive equivalents” where the underlying mood of depression may be denied by its owner and complaint be made only of a somatic symptom. Through non-recognition, this type of case has received poor management by either misguided treatment or brutal dismissal.

A woman of thirty-two years was referred to me as a case of “trigeminal neuralgia,” for which large doses of codeine, trichlorethylene, et cetera, had been given uselessly for over a year. The symptoms were general constant pain in the face, more on the left than right. Also the pain was felt as “the beating of the brain,” and was present too “across the forehead as a tight mechanical band” (a common translation of depression into somatic feeling). Sleep was disturbed, for she spent most of her time in bed and in a partial stupor from drugs. “No the pain is so great I cannot interest myself in anything but to get a little better in the evenings” (again a characteristic of the general rhythm of the manic-depressive constitution).

One became struck with the flat, unemotional facial expression, the personality looked drained away, only the eyes were anxious, with that apprehensive, rather hunted expression produced by raising the inner part of the eyebrows. She denied being depressed,—“but, of course, with this pain, I don’t feel very gay”—thus with an unhumorous “brave” little laugh.

The menstrual period had been very irregular during the time of her illness and had not appeared at all in the four months before examination.

Taking care not to refute the strongly held diagnosis of “trigeminal neuralgia,” I proposed to abolish the pain by what is usually called “electric shock treatment.” I call it “sleep by electric treatment.” And here I would like to pay tribute to the loyalty and openmindedness of her doctor, Dr. Mont Gross, who assented to this peculiar suggestion.

In three treatments she became well. In fact, she was symptom-free after the second,—nor, also characteristically, did she then say, “my pain has gone,” she simply looked young, happy, smiling, and at ease, and never referred to her pain at all. She remained perfectly well—in the family’s phrase, “on the top of the wave,” for eight months, then she was seized with a violent abdominal agony, which “made her roll on the floor.” Diet’s crisis was diagnosed, various treatments were given for two weeks in Florida. Pain was still “terrible” when I then saw her, and her face a dull, middle-aged nonentity. Finding no harmony in her somatic picture, the electric treatment was repeated with exactly the same result as before. Eight months went by. Lately she has been relieved in one treatment of a return, after another eight months’ interval of well-being, of the amorphous facial pain.

This patient has undoubtedly a manic-depressive mood swing with, as often happens, regular timing.

This cyclothymia with three cured episodes has been described in some detail, but many similar instances could be given.

One patient, a middle-aged woman, complaining of right-sided epigastric pain, had been treated from time to time throughout her life for recurrent duodenal ulcer. When depression had been ended, this symptom also evaporated.

Two cases of longstanding numbness and pain around the mouth and nose and teeth were cured in like fashion, they reminded one of the many depressive patients in whom one could know of the imminence of an attack by their sudden anxiety about their teeth, and their rather agitated complaints of queer pains about the hard palate.

Obsessive symptoms, however, can occur on other levels than the somatic.

A middle-aged woman rather quickly changed from being a cheery, efficient wife and mother, to being sleepless and tense, taciturn and mysterious. She muttered dark sayings about “that other woman,” and refused to believe her husband was really not “out on the town,” though he was obviously asleep in the house. She also lost her paranoid delusional system without comment, and resumed her normal ability to command the shop and household.

“Attacks” of obsessional thinking come to mind, about “names” and “numbers.” These often lasted for months at a time and were absent for periods of years between attacks. Those appearing in the past four

years have been ended by evaporating the "supersaturated solution" of depression out of which they'd been crystallized, prior to which the crystal had seemed—as always—more important than the 'fluid' from which it had emerged

Such forced resumption of old superstitious obsessions is as clear a return to a puerile pattern as is the reappearance of a forced grasping reflex which is normal in infants, in an adult with loss of high cortical control by perhaps frontal tumor or cerebral arteriosclerosis

These few descriptions concern persons who, for isolated periods in their lives, think unsurely, often delusionally, feel unsurely often as a protection against the social stigma of being thought insane, and under the whip of their delusions, whether these be in the realm of *ideas* or "*bodily*" symptoms, act unsurely

But what is common to them all? A *mood* of depression and anxiety, a sensation of such deep despair as to require explanation in "rational" or rather "acceptable" terms, compatible with the mores of their society, this to maintain a sense of integration in their own personality. Even those in whom no obsession no "pain" no delusion is crystallized, explain carefully that they are unhappy because they've been a bad mother to the four children," because 'the son is letting the sick man's "tailoring business go to pot," because, of course, of having in youth been guilty of the unpardonable sin ' Neither the husband's reassurance, nor the demonstration of books 'in the black' availed aught with the young mother, or the Jewish tailor of Paterson, New Jersey.

In two depressions five years apart, a great financier whose relationship with a married friend had become accepted after eighteen years' duration, each time loudly blamed his "sin" for his condition. Always on recovery, he resumed his usual way of living. No argument that he had been ill in exactly the same pattern before he ever knew the lady ever penetrated the bulk-headed armor of protection which he built for himself.

The layman always believes these rationalized tales and so do most doctors and very many psychiatrists "So and so went crazy from overwork," "from losing money in Wall Street" "from marrying the wrong woman" "So sad! So easily avoided if men were wise."

Yet I have seen some of the people of whom I have just spoken go through as tragic experiences as can come to us, with fortitude and emotional ability, when such events occurred in their periods of well-being.

What is this terrible recurrent depression which comes to so many in which early patterns of feeling and acting are forced upon the sufferers to be shrewdly explained away so often by dint of use, in intellectual dishonesty their highest faculties of intellect and speech—and they do this, mark you in terror of the consequences the same people, sumably ourselves, would impose upon them.

One observes that only rarely is but one case of such disorder registered in a single affected family, in a group of two or three generations. Most often, over that time, seven or ten persons so afflicted can be identified.

So, it must surely be a thing inherited, innate, and part of the organism itself. After all, if these states could be produced by environmental stress there should have been an epidemic of manic-depressive psychoses, during the last war of four years of terrific slaughter and strain. But there occurred no increase over the peacetime figures.

What Is This Inner Wave, This Recurrent Built-in Pattern, This Rhythmic Flux?—Consider that in the Universe everything exists by reason of its opposite, there can be no light without darkness, nor height without hollow, electricity is positive and negative, systole lives by diastole. Life, as we know it, depends on the balance of power in the organism. We live in health in the unstable equilibrium maintained by the energy tension of our accelerators, the sympathetic system, balanced by our brakes in the parasympathetic. Thus flexibility is gained, whereby environmental changes can be met so successfully that in health the adaptation does not even reach consciousness.

The balance in these forces is delicate, it can be changed, and in every degree. It varies in all of us, but so slightly that most of us stable fellows are hardly aware of those periods in which we are a bit glum, in which work tires us and we begin to waken at 4 in the morning, in which we put off the harder and the newer task, in which we allow ourselves to play with the dream of never trying again to climb the climbing wave, in which we ask ourselves, "Why should we toil, the roof and crown of things?"

Then one day by no discernible fiat, the sun shines better, the gilt again glints the gingerbread, we whistle in the shower and return with a happy hope to the job of work which for long we've wanted to do, but had, for almost as long, postponed.

Such rhythm is normal, all living things live on a pulse, but a good thing can always be overdone. Push the brakes harder and the machine slows down, metabolism is reduced, peristalsis slackens, weight increases, sex decreases, and in the perceiving centers there comes what is interpreted as a vast gloom.

The depression is often not "accepted" by the master of the house, but the sick feelings are resented. The doctor too often fails to understand the pathology of forces by which he is confronted.

Balanced health, this homeostasis as Cannon calls it, must be implemented. *It would seem certain that this control of power and pace is through or in the hypothalamus, the central governor of vegetative rhythm and, I believe, of emotional rhythm as well.*

Illustrative Cases—Let me put two or three cases before you, and please think of their implications.

Katherine M., now aged nineteen years, when she was nine was referred to me by Dr. St. Lawrence. She had fever, headache, stiff neck, at the beginning prolonged light stupor, double vision, and 68 cells in the spinal fluid.

Dr. Tilney and myself had no hesitation in diagnosing her case as encephalitis.

She was in bed for five weeks. When the stupor had cleared, peculiar behavior became manifest. The child, when perhaps sitting up in bed, would be seen within half-a-minute to have become largely immobilized. Her facial expression ceased to be animated, her eyes stared unwinkingly. She would then answer questions in a dull monotonous voice, often making mistakes in her answer to simple questions regarding her age and her address. During this phase she was capable of adding two and two or four and four but made mistakes, or she added quite irrationally without any evidence of thought, nine and four, seven and eight.

The limbs exhibited the waxy flexibility characteristic of certain catatonic states seen in "schizophrenia." The arms if placed in some grotesque and uncomfortable position would remain unsupported and apparently without fatigue, until they were either replaced or she was ordered sharply to put them down.

These episodes at first occurred several times a day and would last from five to forty minutes. They would end about as quickly as they had begun, that is to say, she would blink, rub her eyes, look animated, move about in bed, and perhaps then slip out of bed and run about the room with the childish gestures appropriate to her age. Asked what had been happening to her, she never could tell us more than that she "had felt queer and could not talk right."

After two months these episodes were occurring only occasionally when I ceased to see her, then she went to her home in the Middle West.

Some two years afterwards I heard from friends that she was very well but apparently very nervous. I was therefore not surprised when in September of 1941, I was again consulted because, ever since her original illness, she had been subject to a rhythm of fluctuating energy and emotion. Thus had settled into a constant pattern, nine to thirteen days of elation in which she would look very bright, was greatly animated, was very restless, rarely sat down and then only on the edge of her chair, had bursts of talk, did her lessons at top speed and far more than was required, and slept very little.

On many occasions she was known not to have slept at all for six days and nights, this without any sign of fatigue but with loss of weight.

At the end of this period of elation she would, inside one day, begin to slow up, quiet down, become shut into herself, answer in monosyllables in a low flat voice, work very slowly at her lessons, she would have the general air of a middle-aged faded nun.

This state would last from two to three weeks and was always followed by a period of elation such as has been described.

Clearly she was a manic-depressive with a very rapid mood swing of curious but timed regularity. (There was no history of emotional instability in her family.) For years she had made engagements according to the way she knew she would be when the engagement day came.

She had been unable to remain at boarding-schools because in her elated periods, she had kept all the girls in the dormitory awake by conversation all night and every night and would often insist at 3 in the morning on selling her horse and riding across country.

I was of the opinion, in 1941, that by *electrical treatment* it was possible to cure the *episode*, but that the treatment had no prophylactic value for the future. I therefore did not think it would be advantageous

to administer this treatment to this patient and did not do so till the spring of 1942

She has received only five treatments, administered at the beginning of the elated period. They have always restored the normal rhythm of sleep, and produced tranquillity of emotion and behavior. No treatment has been given, or required, since April, 1943. She has been successfully maintained in boarding school, and her family report her better than she has ever been. In fact, since May of this year, the difference between her period of elation and period of depression could be detected only by members of her family who themselves said that perhaps they only saw anything unusual because they were naturally looking for trouble.

Another case was H. G., seen in consultation with Dr. Malcolm Goodridge in May, 1921. This patient served as a private in the United States Marines during the last war and was supposed to have disintegrated mentally following an alleged attack of influenza in London during the month after the armistice. He was placed in Bloomingdale Hospital for about eight months after his return home. The diagnosis was *dementia praecox*, at that time still the fashionable name for schizophrenia. The clinical picture seen in the spring of 1921 was sufficiently confusing, a young man of splendid physique carried his height of 6 feet 2 inches (188 cm) with a pronounced stoop, an acquisition of his illness. Without syphilis, the pupils were distinctly sluggish to light, the right side of the face flattened in its creases, there was a fine jelly-like but definite nystagmus on lateral conjugate deviation of the eyes to the right or left. There was pronounced tremor in the extended hands. He had lost more than 30 pounds since his illness.

Except for the absence of the abdominal reflexes, great increase in the arm, knee, and ankle reflexes, and involuntary shivering movements of the pectoral muscles, nothing of pathologic interest could be made out in the sensori-motor system. He suffered, however, from severe nocturnal insomnia, rarely sleeping more than two hours before dawn, after which he would usually awaken and again grow drowsy and perhaps sleep, for three or four hours before noon. Whether he had slept or not, during the first part of the day he was utterly inert, and exasperated by his inertia. He had the utmost difficulty, through defective will power and indecision in accomplishing simple acts like shaving, dressing or bathing. He agonized for hours in futile efforts to write a short note or keep an important engagement during the early part of the day. In his mental attitude there was no trace of negativism, he desired passionately to do those things which he could not do at that time, and which later in the day he often could do with relative ease.

There was a distinct resemblance between his inability to perform acts to the completion of which he was urged by will, for which he lacked the stronger adjunct of emotion, and the palsy of purely voluntary movements in midbrain encephalitis of the parkinsonian type—palsies so often abolished by emotional stimulation. He complained frequently of "numb attacks" during which he felt "very cold," and in which he shivered and his teeth would chatter like a man with a rigor. During these attacks, even in July weather, his rectal temperature was always subnormal, on several occasions being 97° F., and on his skin were large patches of gooseflesh which covered a third of the body area at a time and which, under observation, changed their position like a breeze over still water.

In the same general period but not necessarily and indeed rarely at the same

hours, he had attacks of disturbed breathing rhythm of from a quarter to half a hour's duration. During these attacks he felt as though he could not fill his lungs with air (a frequent somatic symptom of depression and inner anxiety) and breathed with all his accessory respiratory muscles from fifty-six to sixty-four times a minute. At other times, he experienced what seemed like a spasm of the laryngeal muscles and breathed more and more stertorously and ineffectively so that the lips were cyanosed and the eyes protruded. Phenomena such as these have appeared at times in hysteria, and various physicians had considered them hysterical in this case. Such explanation, however, could not account for the patient's abnormal thirst for ice water. He consumed for a period of eighteen months between fifty and sixty tumblers of water every twenty-four hours and had proportionate polyuria.

An analysis of the initial illness in December, 1918, which the patient had always considered "influenza," revealed the only symptom to have been "severe headache and intense sleepiness by day and by night." Two negative features of value, however, were that he had had no feeling of fever and that he had never reported sick to a medical officer. It is highly unlikely that this could have been true of any youthful patient with the "influenza" which was really "evanotic pneumonia" prevalent in London at the end of 1918. Furthermore, after three or four weeks, sleepiness disappeared during the night time and was present only by day—a reversal of the sleep mechanism sufficiently familiar to all students of epidemic encephalitis.

The patient's symptoms during the last eight months of his illness gradually improved to almost normal, with little or no morning inertia, no difficulty with respiration and no rigors, polydipsia was reduced to an intake of only three quarts of water a day.

A boy of fourteen years had a similar polydipsia and polyuria, tremors in the upper extremities, excessive salivation and similar distressing paroxysmal attacks in which breathing was exceedingly rapid, labored and difficult. At these times there was great emotional distress and suffering. The boy had acute encephalitis in January, 1920, with visual disturbance, diplopia, fever and excessive incontinence. This was followed for many months by apparent recovery and was gradually succeeded by a rhythmic incessant cough, and stammering of speech and thereafter by the distressing symptoms already described.

THE ROLE OF THE HYPOTHALAMUS IN MANIC-DEPRESSIVE PHYTHMS

The integrating mechanism of the diffusely working sympathetic and the discreetly working parasympathetic are linked and may be activated by hormonal messengers chiefly from the hypophysis, through the two vascular systems carrying blood from the capillary bed of the posterior lobe to the capillary bed of the tuber and supraoptic nuclei. The hypothalamus is a neuroglandular instrument in control of vital rhythm. The timing of the organism is placed there, control of heart rate, of breathing, of water balance, of the cycle of sleep and constancy, of weight and temperature and the rhythm of the nervous

The ebb and flow in mood, behavior and the emotional expression follows stimulation or depression of these areas

Foerster produced the symptoms of acute mania when he set in motion a tumor pressing from below the walls of the third ventricle In another case, when he wiped blood from the third ventricle walls, manic excitement at once occurred

Ranson states that "the fact is no longer doubtful that a manic condition can be produced by mechanical stimulation of the oral part of the hypothalamus in man, and that these symptoms cannot be produced from any other spot "

On the other hand, interference with the posterior hypothalamus is followed by sleep and unconsciousness

The character of these hypothalamic rhythms is like our fingerprints, superficially identical, in detail utterly specific for each individual They would appear at first sight, to be under the control of the conscious ego, and influenced by surrounding conditions But so do the Atlantic rollers seem to be made by the wind and the weather These, however, only change the appearance of the top of the roller The great wave itself, propagating its energy for thousands of miles across the sea, is really made by another force of which the observer cannot be conscious, namely, the rotation of the earth

THE INSTABILITY OF MOODS

Change in the balancing of nervous energy is only occasionally massive, producing either total depression or total elevation of the whole organism Changes may be, not total, but fragmentary—just as *petit mal* is a fragment of the whole convulsive phenomenon, or a spasmed hand or spasmodic torticollis is a fragment of a general dystonia So, the unbalance between sympathetic and parasympathetic may operate on different integration levels, giving rise to circulatory asthenic symptoms here, and to disordered digestive processes there, all to be interpreted through a mist of fear and depression by the intellect, a recent arrival in command, uncertain in decision, using for expression the new tool of an inadequate vocabulary, and liable in crises to divebomb for an overdefinite answer to a magic level, laid down in childhood by the anxieties of two million years

So, the uncertainties of feeling, of thinking and describing, and of acting, come from unbalance in the forces by which we live, by which we are permeated, which we inherit

We each possess a prevailing mood—which may be inherently unstable or made so by exogenous disease That mood and its changes are interpreted by our conscious thoughts and described with the faltering and inadequate noises of speech

The psychologist makes much, in fact all, of "speech " His criteria is what he is told and he interprets this into such other terms as he

pleases—often under a smoky lamp. The physiologist leaves out subjective description and latent anthropological levels and interprets all in terms of reflexes or chemistry. The nutritionist snaps his fingers, and rightly enough, for attention to the accessory food factors and caloric values. But the wise observer must gather news from each expert. He will decide that the *mood* is the source of action—feeling and thought, is dominant and often unstable. In unstable periods the conscious mind often has no capacity for integrative action—misunderstands, explains badly, and runs for cover and help to a latent cultural level of thought and feeling.

To avoid these unhappy things, a man must first be well born and well fed. Good brain begets good mind. Then he must be well taught—to develop fortitude which includes independence, and humor which gives courage by a sense of proportion and an educated philosophy which, as the Greeks had it, enfolded all else. He must develop a personal integrity which knows itself to be without self-reproach or fear.

He will then be able to live with his innate emotional pattern without overmuch disturbance if the forces making the pattern remain in balance.

THE VALUE OF ELECTRIC THERAPY

For those whose pattern is hereditarily unbalanced, for those having good pattern but unfitted by education to live with it, or for those whose patterns have become diseased, help can sometimes be found only in the modern electric therapy.

As yet we use insulin, metrazol and electric sleep therapy to alter the balance of chemical and physical forces in a manner largely empiric. We know from thousands of cases that the passage of from 80 to 150 volts of electric current for a tenth of a second through the brain produces an often miraculous alteration for the better in mood and obsessive thinking, and that agitated depression—even though accompanied by a delusional state, can by this means be replaced by a happy tranquillity and clear-eyed insight, and further, that mood of elation and even mania grow quieted to a normal level.

How is this extraordinary result brought about? Clearly in the depressed cases the sympathetic is hugely stimulated, a balance between opposing energy forces is struck and normal rhythms reestablished—even those of sleep and menstruation are renewed.

However, only our five senses prevent us from perceiving that matter and mind are merely different forms of the same things. In truth we are geometric aggregations of force molecules, probably each with his individual pattern, derangement of which changes mood and the intramural radioactivity that we call thought. Why electric treatment should reestablish the normal energy balance and pattern rather than still further disturb it will no doubt be discovered—given Peace in our time.

So, our attitude is more a biopsychic approach than a mechanistic approach. We must believe that we cannot have intellect or ecstasy without a good neuronic endowment.

The strategic outlines and boundaries of mind are laid down by what we call physical heredity—its tactical plan by social inheritance, by education, and by the molding pressures of sex, the herd and hunger. All may be destroyed by infection, or injury or degeneration.

We are now only picking at the locks of doors behind which lie the answer to these mysteries. Many keys will be needed for the opening, but it surely will not be beyond man's wit to make them.

We have in this physical therapy an attack on mental illness which means to the treatment of disorders of the "mind" what the appearance of Lister's carbolic spray meant to surgery.

CHRONIC ENDOCRINE DISORDERS

WILLARD O THOMPSON, M.D., F.A.C.P.*

Most endocrine disorders are chronic in the sense that they commonly persist until specific treatment is carried out and those involving hypofunction of glands of internal secretion usually recur when specific treatment is omitted. It will, therefore, be impossible in the space allotted to cover in detail the whole field of chronic disorders of the endocrine glands. Emphasis will be placed on those disturbances with which the practicing physician is most often confronted.

THE THYROID

Hypothyroidism—Once a deficiency of the thyroid develops, it usually persists throughout life and its manifestations will usually reappear gradually when the administration of desiccated thyroid is discontinued. The signs and symptoms that develop on omission of treatment are always similar in the same patient except in the case of cretinism. In this condition the administration of thyroid may produce such great changes in the patient that some manifestations of thyroid deficiency which follow the omission of treatment may vary at different ages in the same patient.

DIAGNOSIS—Cretinism and myxedema are not commonly encountered by the average physician, with the result that the diagnosis is often not made until the disease has been present for a considerable

To the trained observer the diagnosis of full blown *myxedema* is not difficult. To the average physician, however, it presents some difficulty because of its rarity. It is still confused with chronic nephritis, particularly the nephrotic variety, with anemias of various sorts and with Simmonds' disease (pituitary cachexia). It is sometimes confused with chronic nephritis because some older patients with myxedema may have hypertension, transient albuminuria and secondary anemia. The characteristic myxedematous facies is absent in chronic nephritis as well as the dryness of the skin, thickness of the tongue and slow, thick characteristic speech. Some patients with myxedema develop edema of dependent portions of the body and in some it may be extreme and result in marked ascites, thereby causing the disease to be confused with nephrosis in which the basal metabolism is also often very low. However, the concentration of serum protein is normal in myxedema, and there is no reversal of the albumin-globulin ratio as in nephrosis.

Some degree of secondary anemia is commonly present in patients with myxedema, and occasionally myxedema and pernicious anemia coexist in the same patient. The anemia per se, however, does not produce the clinical appearance of myxedema. It is usually necessary to give specific treatment for both anemia and myxedema in order to correct them. Occasionally patients with myxedema are thought to have a brain tumor because of the presence of ataxia and a high concentration of protein in the cerebrospinal fluid. The cerebrospinal fluid does not show other abnormalities. During the administration of thyroid the concentration of protein in the fluid promptly drops to within normal limits.

TREATMENT—Myxedema develops insidiously over a period of many years. Two serious errors may be made in treatment. (1) The initial dose of desiccated thyroid may be too large so that unpleasant and sometimes harmful effects are produced. There is great danger in older people of inducing a coronary thrombosis by the initial administration of too large doses. (2) Failure to continue treatment.

The treatment of primary hypothyroidism may be outlined as follows¹

- 1 Administer the minimum amount of *desiccated thyroid* necessary to maintain a normal level of metabolism. The average dose required for maintenance in adult thyroidless individuals is from 1½ to 2 grains of USP thyroid daily (0.18 to 0.23 per cent iodine). The dosage for cretins is noted above.

- 2 Begin with a small dose (1 grain daily in adults) and increase gradually after several weeks until the correct amount is being administered.

- 3 Changes in the dose should be made slowly because of slow adjustment. At least two months is required for complete adjustment to any dose.

4 Avoid large initial doses in all patients, particularly in those with arteriosclerosis and coronary disease. In such patients the initial dose should not exceed $\frac{1}{2}$ grain daily, and it may be necessary to adjust the metabolism at a slightly subnormal level because of the inability of the heart to meet the demands placed upon it by a normal level.

5 *Thyroxin* has no advantage over desiccated thyroid in the treatment of myxedema except in rare instances. Any attempt to correct the disease quickly by the initial administration of thyroxin intravenously not only may make the patient very uncomfortable because of muscle tenderness but may be very harmful. If an initial dose of desiccated thyroid is too large, muscle tenderness may be so great that the patient is unable to sleep.

From the standpoint of hypometabolism the problem that confronts the physician most is the matter of diagnosis and treatment in patients who have a moderate depression of the basal metabolism (from minus 15 to minus 25 per cent) but who do not appear to be myxedematous. In some of these patients there is present a mild hypothyroidism that is primary in type, in others there is a mild hypothyroidism that is secondary to a deficiency of the anterior lobe of the pituitary. In others the cause of the low metabolism cannot be determined at the present time. In many of them it is possible to determine the presence or absence of hypothyroidism only by a therapeutic test with thyroid. If the patient is improved when given the minimum amount of desiccated thyroid that is necessary to raise the basal metabolism to normal it may be assumed that some hypothyroidism is present and the administration of desiccated thyroid necessary. However, if the patient does not improve, its administration is futile and may even make the patient worse.

Hyperthyroidism—Hyperthyroidism once it appears commonly persists for years unless the disease is abolished by appropriate therapy. The intensity of the disease often varies in the same patient from time to time, particularly when it is of the exophthalmic goiter type. In some instances the remissions may be so great that the basal metabolism drops to a subnormal level and clinical evidences of hypothyroidism appear. This spontaneous substitution of the hypothyroid state for the hyperthyroid one may be followed by the reappearance of hyperthyroidism. Remissions and relapses may go on for years. In other patients the disease appears to remain in a steady state with approximately the same elevation of the basal metabolism persisting for long periods of time.

Postoperative Thyrotoxicosis—Of particular interest is the persistence and recurrence of toxic goiter following subtotal thyroidectomy. In many well run thyroid clinics the incidence of postoperative thyrotoxicosis varies from 5 to 15 per cent. Why the disease should be abolished in most cases by a subtotal thyroidectomy but not in others is

not entirely clear. In some instances inadequate removal of the thyroid plays a role, but in others rapid regeneration of thyroid tissue occurs in spite of adequate subtotal thyroidectomy. In some patients, records show that the disease is not completely abolished by three or four subtotal thyroidectomies. In such patients it would appear that the cause of the disease is acting with great intensity and is not eliminated by the thyroidectomy.

It should be pointed out that postoperative thyrotoxicosis usually represents a persistence of the disease and only occasionally a recurrence. This means, of course, that once the basal metabolism drops to within normal limits following the thyroidectomy and remains there for as long as one month when the patient is not receiving iodine, it is unlikely that the patient will ever be thyrotoxic again. In rare instances a recurrence may be observed months or years after the operation. Thyrotoxicosis following subtotal thyroidectomy behaves in the same manner as the untreated disease and is characterized in some patients by remissions and relapses. The management of the condition differs only slightly from that of the untreated disease.

TREATMENT—In most instances it is desirable to perform a *subtotal thyroidectomy* after adequate preparation of the patient. In a few others it may be possible to maintain the basal metabolism within normal limits by the administration of iodine until the disease disappears. It should be pointed out that the danger of complications, notably recurrent laryngeal nerve paralysis and parathyroid tetany, is much greater with the second and third than with the first thyroidectomy. In some instances in which one vocal cord is paralyzed and most of the palpable thyroid tissue is present on the opposite side, it may be desirable to use roentgen-ray therapy instead of resorting to further surgery. In general, however, the treatment of toxic goiter by irradiation of the gland is a very unsatisfactory procedure.

Of great interest are recent experiments on the control of toxic goiter by nonsurgical methods, particularly by the use of *radioactive iodine* and by the administration of *thiourea* and *thiouracil*. Sometimes during the prolonged administration of the thyrotropic factor of the pituitary, the basal metabolism will drop to within normal limits after an initial rise. There are many reasons for believing that the treatment of toxic goiter will eventually be accomplished by medical and not surgical procedures. However, these recent observations are still in the experimental stage and the best routine method of managing the disease still remains the performance of a subtotal thyroidectomy after adequate preoperative preparation of the patient.

THE PARATHYROIDS

Hypofunction and hyperfunction of the parathyroid glands are not very common and when they develop are usually cared for in special

clinics. However, both conditions may be encountered by any practicing physician. He must, therefore, be somewhat familiar with their signs and symptoms.

Hypoparathyroidism (Tetany)—Hypofunction of the parathyroids in most instances follows the removal of the parathyroid glands at the time of a thyroidectomy. It occasionally follows the removal of too much parathyroid tissue during a parathyroidectomy for hyperparathyroidism. In rare instances, a spontaneous form of the disease is seen which corresponds to spontaneous myxedema. The disease may vary greatly in severity, depending upon the extent of hypofunction. Acute and chronic forms are observed. Acute manifestations of the disease are noted when the function of the parathyroids is suddenly withdrawn, as following a parathyroidectomy. As time goes on, one of two things may happen. Some regeneration of parathyroid tissue may occur so that the hypofunction may be partially or completely relieved. It is more common for some degree of hypofunction to persist. The body gradually adapts itself to the loss of parathyroid function so that the symptoms of the disease in its chronic form are not so severe as in the acute form.

DIAGNOSIS—The most important *clinical signs* of tetany are numbness and tingling of the extremities, which may or may not be accompanied by pain, the signs of Chvostek and Trousseau, lowering of the concentration of calcium in the serum, and increase in the concentration of phosphorus while the phosphatase remains normal. The excretion of both calcium and phosphorus is low in the urine and normal in the stools. Erb's phenomenon, which is caused by increased nervous excitability, can be elicited only by special equipment which is rarely used in the practice of the average physician.

In general, the intensity of signs and symptoms is proportional to the degree of lowering of the concentration of the serum calcium, although there are exceptions to this rule. Occasionally a patient with extreme lowering of the calcium value will suddenly develop tetanic convulsions without showing either a Chvostek or a Trousseau sign and without complaining of any numbness. However, hypoparathyroidism is almost always detected before it progresses to the state of tetanic convulsions and no patient should die at the present time from parathyroid tetany. In general, it may be said that the development of convulsions in this disease indicates poor management.

The signs and symptoms of tetany usually do not develop until the concentration of calcium in the serum drops to about 7.5 mg. per 100 cc., although the actual level varies somewhat from patient to patient. In most patients with complete hypoparathyroidism the concentration of calcium drops to between 4 and 5 mg. per 100 cc. It should be emphasized that the determination of the serum calcium is not very valuable unless it is accompanied by the determination of the

concentration of the serum protein. About one half of the calcium in the serum is bound by protein and it is the ionized or diffusible calcium that is of primary importance in tetany. For this reason, the concentration of calcium in serum may be low without any symptoms of hypoparathyroidism being present. This phenomenon is seen in patients with nephrosis.

COMPLICATIONS—The most serious complication of untreated hypoparathyroidism is the development of bilateral *cataracts*. These do not seem to appear except in the more marked forms of the disease, and they do not appear at all if adequate treatment is given. It is, therefore, very important in treating patients with tetany to be sure that the treatment is adequate to maintain the calcium in the serum within normal limits and that the eyes are examined periodically to make sure that cataracts are not developing.

Some *spasm of the vocal cords* may be present in patients with parathyroid tetany. This is particularly evident in patients who have paralysis of at least one vocal cord. The same operative procedure that results in injury to the parathyroid glands may also result in injury to one of the recurrent laryngeal nerves. Consequently the association of parathyroid tetany and unilateral vocal cord paralysis is a common one. The symptoms produced by the paralysis are aggravated by the spasm resulting from parathyroid tetany.

TREATMENT—In treating the chronic form of the disease, parathyroid extract is not used and it is rarely used at the present time in the acute stage immediately following operation. The following procedures have proved most useful for prolonged management: (1) Administration of from 45 to 90 grains of *calcium lactate* or *calcium chloride* per day. This is administered in three equal doses. The first one is given with breakfast, the second about the middle of the afternoon and the third at bedtime. (2) Administration of some material that promotes the absorption of calcium from the gastro-intestinal tract. The best material for this purpose is *dihydratichysterol*, which is given in doses of 1 cc. two to four times per week. Large doses of vitamin D₂ such as 50,000 U.S.P. units daily are also of value but perhaps not quite as effective as dihydratichysterol. The object of treatment is to maintain the level of serum calcium within normal limits (9 to 11 mg. per 100 cc.). As a rule, when the patient feels well, the concentration of calcium is normal but this is not necessarily the case. The disease cannot be managed satisfactorily without laboratory facilities for determining the concentration of serum calcium. This is a comparatively difficult determination technically and the results obtained in many laboratories are often fictitious.

Hyperparathyroidism—Hyperparathyroidism is a rare disease, although a considerable number of cases have been reported in some

special clinics. It is usually present for years before it is recognized and is often detected only after serious damage is done to the body. In most instances it is not discovered until there have developed multiple bone cysts (*osteitis fibrosa cystica*), spontaneous fractures, collapse of the vertebrae, renal calculi or giant cell tumors. The damage done by collapse of the spine cannot be repaired and chronic nephritis may develop in the more chronic cases of renal calculi.

DIAGNOSIS—Hyperparathyroidism should always be thought of in patients with unexplained muscle weakness, hypotonia, lack of appetite, nausea, constipation, pain in the bones and polyuria. The most important diagnostic sign is the presence of a high concentration of calcium in the serum. The concentration of phosphorus is low and that of the phosphatase is high. The excretion of calcium and phosphorus in the urine is high but normal in the stools. The diagnosis usually can not be definitely established by laboratory procedures unless the concentration of calcium in the serum is 12 mg. per 100 cc. or more. Careful roentgen ray examination of the skeleton is important although thinning of the bone and the development of multiple bone cysts may be prevented by the drinking of large quantities of milk. It is wise to make serum calcium determinations in all patients with renal calculi, particularly in those with recurrent stones.

Nodules may often be palpated in the region of the thyroid although they are usually not as large as thyroid adenomas. However they may sometimes be very large and they vary greatly in position. All of the parathyroid tumor is sometimes in the mediastinum just as in the case of some thyroid tumors.

TREATMENT—Treatment consists in the removal of an adequate amount of parathyroid tissue. Certain practical difficulties are encountered in this procedure. The number of parathyroid glands varies from one to fourteen and it is not always easy to find the offending gland or glands. An effort should always be made to determine where the parathyroid tumor is and to confirm the diagnosis by frozen section at operation and then to perform a subtotal parathyroidectomy. The development of parathyroid tetany after operation is common but this condition may be only temporary.

Following operation the concentrations of calcium and phosphorus in the serum usually return to normal fairly promptly, but the concentration of phosphatase becomes normal more slowly. In order to replace the calcium and phosphorus which have been lost from the skeleton, it is desirable to administer large quantities of these minerals as well as an adequate amount of vitamin D for many months. The objects of treatment are to prevent permanent damage to the skeleton and to prevent the development of renal calculi and chronic nephritis.

ANTERIOR PITUITARY

The most important of the chronic diseases of the anterior lobe of the pituitary are dystrophia adiposogenitalis (Frohlich's syndrome), Simmonds' disease, chromophobe adenoma, dwarfism, acromegaly and pituitary basophilism (Cushing's syndrome)

Dystrophia Adiposogenitalis—The term "dystrophia adiposogenitalis" is a general one which applies to the disease in both children and adults, whereas the disease in children is known as the Frohlich syndrome. This condition is characterized in the male by obesity, hypogonadism and genu valgum. The shoulders are narrow, the breasts full, the abdomen large with a characteristic transverse fold just above the pubic area, the hips are broad and the forearms and lower extremities are often not much increased in size in contrast to the great excess of weight in the middle portion of the body. In only a few of the patients is cryptorchidism present. In the female the breasts may be poorly developed, one may be larger than the other or they may be normal in size but contain an excessive amount of fat tissue. The disease is sometimes but not very often associated with dwarfism, particularly if a pituitary tumor is present. In most instances the sella turcica is normal in size.

In some patients of this type, a complete transformation will occur at the time of puberty without treatment. In others, the condition persists throughout life. The diagnostic criteria are inadequate at present.

TREATMENT—It is probably wise to carry out treatment in all individuals in whom the hypogonadism is marked. It should be started between the tenth and twelfth years and continued until epiphyseal union is completed. *In the male*, the treatment consists of the administration of from 500 to 1000 international units of chorionic gonadotropin three times weekly. Sometimes with the administration of this material alone, complete transformation of the body contour occurs and no other form of therapy is necessary. In others, it may be necessary to supplement this form of therapy with a weight-reducing diet, and if the basal metabolism is low, with the administration of desiccated thyroid. *In the female*, the administration of chorionic gonadotropin does not appear to be as effective as in the male and in the more marked forms of the disease it may be necessary to use female sex hormone to influence skeletal molding and induce sexual maturity.

When the disease is not detected until later in life, a considerable amount of improvement may be produced in men by the administration of chorionic gonadotropin and a weight-reducing diet as above noted. However, the skeletal contour cannot be affected. In women, gonadotropic substances are not notably effective and as a rule some form of estrogenic material must be used.

Simmonds' Disease—Simmonds' disease or *pituitary cachexia* is a rare disorder in which there is a complete loss of all functions of the

anterior lobe of the pituitary, commonly following an infection. It is characterized by extreme weakness, loss of weight, lowering of the basal metabolism, lowering of the concentration of sugar in the blood (which may be so extreme that hyglycemic convulsions occur), loss of memory, anemia and hypogonadism with loss of sex function

The disease is often confused with anorexia nervosa and most patients that have been reported to have Simmonds' disease have probably actually suffered from anorexia nervosa. Patients with Simmonds disease appear seriously ill whereas those with anorexia nervosa appear comparatively well in spite of the extreme loss of weight

Some improvement may be produced in Simmonds disease by the correction of the hypogonadism with suitable gonadotropic material or sex hormone, by correcting the hypothyroidism and by administering a high caloric diet.

Chromophobe Adenoma—The chromophobe cells are inert and chromophobe adenomas are therefore commonly associated with underfunction of the pituitary, particularly when they are large enough to compress or replace the normal tissue. They vary greatly in size and the symptoms associated with them usually persist until adequate treatment is carried out.

DIAGNOSIS—The symptom complex depends upon the degree of loss of pituitary function and upon the presence or absence of pressure on the structures above the sella turcica notably the optic chiasm and the hypothalamic area of the brain.

Signs and Symptoms Related to Underfunction of the Anterior Lobe of the Pituitary—1 Hypothyroidism (secondary) The basal metabolism may drop to as low a level as in patients with complete absence of thyroid function, namely minus 40 to minus 50 per cent, but the clinical picture is different from that seen in myxedema. The rough, dry, scaly skin and the typical myxedematous facies are absent. The skin is usually smooth and soft and the hair is of fine texture.

2 Hypogonadism (secondary), with atrophy of the genitalia azoospermia and amenorrhea

3 Change in sugar metabolism with flattening of the sugar tolerance curve and a reduction of the fasting blood sugar

4 Obesity is commonly but not necessarily associated with the condition. When present it may be related to a disturbance in the base of the brain.

Effects of Pressure on the Optic Chiasm—The most common effect of pressure on the optic chiasm is a bitemporal hemianopia which at first involves the upper quadrants and later becomes complete. Finally the whole optic nerve degenerates and blindness ensues. The tumor may, of course, grow laterally and compress only one optic nerve producing a contralateral homonymous hemianopia. When the tumor breaks through the dural diaphragm it may encroach on the floor of

the third ventricle, producing various symptoms. In some instances it may extend far enough to block the third ventricle, therefore producing an internal hydrocephalus. In rare instances it may compress the third, fourth and sixth nerves, producing an extra-ocular palsy or it may invade the temporal lobe, producing uncinatc seizures.

TREATMENT—The symptoms associated with chromophobe adenoma of the pituitary usually persist throughout life unless specific treatment is given. In some patients definite improvement may follow *removal* of part or all of the adenoma, or release of the cystic fluid which it may contain. Such improvement is probably related to removal of pressure from the normal pituitary cells. Surgical intervention is indicated only when the tumor extends through the roof of the sella turcica and invades the structures lying just above it, particularly the optic chiasm. Roentgen ray therapy is of little value in this condition.

It is necessary to treat the hypopituitarism regardless of whether or not surgical measures are indicated. This is best done by treating the glandular hypofunctions that are secondary to the hypopituitarism, inasmuch as there is no pituitary extract that is very effective clinically. Great improvement may follow the treatment of the hypothyroidism with *desiccated thyroid* and the treatment of the hypogonadism with *stimulation* or *substitution therapy*. As obesity is commonly an associated condition, administration of a suitable weight-reducing diet may constitute an important part of the treatment.

Dwarfism—Pituitary dwarfism may persist indefinitely because there is no preparation of the growth factor of the pituitary that has much effect in man. It may be associated with a chromophobe adenoma, or no tumor may be present at all. The deficiency of growth factor must develop during the active growth period in order for dwarfism to result. All degrees of the condition may be noted, depending upon the severity of the pituitary deficiency and the age at which it begins. It is commonly associated with a deficiency of other functions of the pituitary, notably the thyrotropic and gonadotropic functions, but this is not necessarily the case. Growth factor is produced by the eosinophilic cells and the gonadotropic factor by the basophilic cells. It is therefore possible to have a pituitary dwarf with normal development of the genitalia and normal sex function, just as it is possible to have the reverse condition, namely eunuchoidism secondary to a deficient production of gonadotropic factor in an individual who is normal in height and whose pituitary therefore produces an adequate amount of pituitary growth factor.

TREATMENT—Although preparations of the growth factor are not particularly effective clinically, a considerable amount of skeletal growth may be induced in the male pituitary dwarf by stimulating the testes to produce male sex hormone, with *chorionic gonadotropin* or by the administration of *male sex hormone* itself. In order for this

material to produce its maximum effect, treatment must be started not later than the age of ten to twelve years. The amount of skeletal growth that can be induced in this manner is limited and if the dwarfism is extreme the skeleton will never achieve normal height regardless of the age at which treatment is started.

Acromegaly—Acromegaly is a disease of long duration. There are instances on record in which it has lasted for fifty years. It is usually caused by an eosinophilic adenoma of the pituitary, although it may be the result of hyperplasia of the eosinophil cells without the presence of an adenoma. The disease is rather frequently associated with overproduction of the thyrotropic factor and overproduction of the diabetogenic factor, so that syndromes resembling exophthalmic goiter and diabetes mellitus respectively are produced. The high basal metabolism in this condition shows some reduction during the administration of iodine and the diabetes is controlled with insulin just as it is in patients who do not have acromegaly.

DIAGNOSIS—There is little difficulty in making a diagnosis when the disease is well advanced. There is overgrowth of all the tissues in the body resulting in characteristic changes in the face, hands and feet. It is not often that the diagnosis is made in the early stages.

TREATMENT—The size of the sella turcica varies greatly but the adenoma is rarely large enough to demand surgical intervention, the only indication for which is pressure on the optic chiasm or on the floor of the third ventricle. In rare instances all the characteristic manifestations of invasion of the hypothalamic area may ensue. Unless surgery is indicated, *roentgen ray therapy* is the treatment of choice. This form of therapy is unsatisfactory and it is very difficult to tell when the disease is quiescent and when it is progressive. Skeletal changes may increase in spite of the presence of a normal level of basal metabolism and the absence of diabetes.

In some patients, severe headache is a very prominent feature and it may be very refractory to treatment. Chronic hypertrophic arthritis and renal calculi are not uncommon complications of acromegaly.

Pituitary Basophilism (Cushing's Syndrome)—A few years ago Cushing described a disease characterized by the following manifestations: obesity, hypertension, glycosuria, purplish striae in the abdomen, thighs and chest, hypogonadism (with amenorrhea in the female), hypertrichosis, weakness and increased excretion of nitrogen in the urine. The condition is commonly fatal although the patients may live for several years. According to Cushing's interpretation the disease is the result of a basophilic adenoma of the pituitary which may be microscopic in size. Other investigators have claimed it to be the result of an adenoma of the adrenal cortex which is found in a fairly large percentage of the patients.

TREATMENT—Some improvement has been reported in a few cases

stances following irradiation of the pituitary and following removal of basophilic adenomas of the pituitary and adenomas of the adrenals. Improvement has also been reported following the administration of male sex hormone, which causes storage of protein.

THE POSTERIOR PITUITARY

Diabetes Insipidus—Diabetes insipidus is a rare disease but is occasionally encountered by the general practitioner. There are many reasons for believing that it is the result of a lesion in the base of the brain above the pituitary and not directly the result of a lesion in the posterior lobe itself.

Diabetes insipidus is characterized by excessive polydipsia and polyuria, with the passage of as much as from 12 to 14 liters of urine per day. The urine is of necessity of low specific gravity and water is eliminated from the body almost as fast as it is absorbed. The hormone of the posterior pituitary has some direct action on the kidney which results in the retention of water.

In rare instances the disease may be associated with hypofunction of the anterior lobe, with or without a pituitary tumor, although diabetes insipidus is not a common accompaniment of disturbances of the anterior lobe. The symptoms of the disease depend upon what involvement, if any, there is of the anterior lobe and of the hypothalamic area. The patients may be thin or obese.

TREATMENT—The disease is best treated by the *insufflation of desiccated posterior pituitary powder* into the nasal cavities. This procedure must be carried out six or eight times during the day in order to promote fairly continuous absorption. Two principles have been isolated from the posterior lobe, one having pressor and water-retaining properties (pitressin) and the other having oxytocic properties and causing the contraction of smooth muscle (pitocin). In actual practice, pitressin is rarely used in the treatment of diabetes insipidus.

THE ADRENALS

Addison's Disease—The most important chronic disorder of the adrenals is Addison's disease, which invariably persists once it develops. It is caused by tuberculosis of the adrenals in about half of the patients and by atrophy in most of the remainder, resulting in destruction of the adrenal cortex. Without treatment, the disease is characterized by remissions and relapses and a gradual downhill course. The patient finally dies in a relapse or crisis from six months to fourteen years after the onset.

DIAGNOSIS—Among the more important manifestations of the disease are the following: (1) brownish pigmentation of the skin and buccal mucosa, (2) weakness, (3) loss of weight, (4) hypotension, (5) anorexia, nausea and vomiting, (6) reduction in the concentration of

sodium, chloride, carbon dioxide and sugar in the serum, (7) increase in the concentration of potassium and nonprotein nitrogen in the serum, and (8) increased excretion of sodium and chloride in the urine

In a crisis all of the signs and symptoms of the disease are exaggerated but the most outstanding manifestations are nausea, vomiting and hypotension. Nausea is always to be regarded in the most serious manner and means that adequate treatment must be instituted at once.

TREATMENT—A crisis is treated as follows:

- 1 Administration of from 10 to 40 cc. of adrenal cortex extract intravenously every hour
- 2 Intravenous administration of 5 per cent dextrose in Ringer's solution at the rate of 1 liter in eight hours

If desoxycorticosterone acetate has been used in treatment the daily dose is continued throughout the crisis and supplemented with the forms of therapy just described. As nausea subsides the patient is given food and fluid by mouth and the dose of cortical extract is gradually reduced. The patient is finally put on a *maintenance program* which may consist of any one of the following procedures:

- 1 Subcutaneous administration of from 10 to 40 cc. of adrenal cortex extract daily in divided doses.
- 2 Subcutaneous administration of smaller amounts of adrenal cortex extract supplemented by sodium salts.
- 3 Subcutaneous implantation of pellets of desoxycorticosterone acetate (the initial implantation usually does not need to exceed 450 mg.)
- 4 Daily intramuscular injection of desoxycorticosterone acetate in a dose of from 5 to 20 mg.
- 5 A combination of smaller doses of desoxycorticosterone acetate and sodium salts.

The best results are obtained with large doses of adrenal cortex extract without supplementary salt therapy, but this form of treatment is very expensive.

In a few patients the response to desoxycorticosterone acetate is unsatisfactory. Among the complications of its use may be mentioned generalized edema and hypertension, focal necrosis of the heart muscle, sudden death from myocardial failure and flaccid paralysis of the extremities. A few patients cannot tolerate this material and must therefore receive adrenal cortex extract. When it is effective, the most economical and time saving method of administration of desoxycorticosterone acetate is in the form of pellets placed in the subcutaneous area. One implantation lasts from six to nine months.

Desoxycorticosterone acetate affects the metabolism of sodium and potassium but does not have any effect on sugar metabolism. Corticosterone does affect both functions, while compound I affects primarily the sugar metabolism.

Patients with Addison's disease are particularly susceptible to the development of upper respiratory infections, and every infection is to be regarded seriously because it appears to increase the demands placed upon the adrenal glands. With adequate treatment, it would appear possible to keep these patients alive for many years.

THE OVARIES

The problem of most importance is that of hypofunction. For an intelligent understanding of deficient function of the ovaries and testes certain general principles must be borne in mind. An intimate relationship exists between the anterior lobe of the pituitary and the gonads. Gonadotropic materials are produced in the pituitary which influence ovarian and testicular function. A follicle-stimulating principle stimulates the growth of the graafian follicles in the ovary and influences the function of the seminiferous tubules in the testis. A luteinizing principle causes luteinization of the developing follicles in the ovary and stimulates the interstitial cells in the testis.

Hypogonadism may be primary or secondary, depending upon whether or not the defect is present in the gonads or elsewhere, notably in the anterior lobe of the pituitary. In a similar manner, hypogonadism may be treated either by stimulating the gonads with suitable gonadotropic material or by substituting for it with the appropriate sex hormone. The type of treatment used depends upon the type of hypogonadism present and upon the activity of the therapeutic agents available. Most cases of hypogonadism appear to be secondary in type.

Three varieties of gonadotropic material are available for *stimulation therapy*:

- 1 Pituitary gonadotropin prepared from the pituitary itself
- 2 Equine gonadotropin prepared from the serum of the pregnant mare
- 3 Chorionic gonadotropin prepared from the urine of pregnant women (arises from the chorionic villi of the placenta)

Pituitary and equine gonadotropin are theoretically desirable as stimulating agents because they contain both follicle-stimulating and luteinizing material. In actual practice they are not especially effective. Chorionic gonadotropin is luteinizing in nature and is very effective in stimulating the interstitial cells of the testis, and therefore, in the treatment of secondary hypogonadism in the male. It is not especially effective in the female, and in the male it has the disadvantage that it does not stimulate spermatogenesis. The status of stimulation therapy in the female is not satisfactory, and in many instances in which this form of treatment is indicated, substitution therapy must be used because effective stimulating agents are not available. Very active preparations of the male and female sex hormones are obtainable in the form of testosterone propionate and various esters of estradiol, respectively.

Secondary Hypoovarianism—Stimulation therapy is theoretically indicated in all cases of hypoovarianism which are secondary to *hypopituitarism*. This abnormality is seen most commonly in women who have scanty or delayed menstruation, or both. The intermenstrual periods are usually prolonged and menstruation may be completely absent. Obesity is usually but not necessarily present. The external genitalia and the uterus may be poorly developed or they may be normal in size. The breasts are commonly within normal limits but the areolae and nipples are pale and poorly developed or atrophic. Axillary and pubic hair may be scanty.

TREATMENT—It is always wise first to try stimulation therapy with *pituitary* and *equine gonadotropin* and then resort to substitution therapy with *female sex hormone* if the former are ineffective. If substitution therapy is used, it is wise to combine it with *progesterone* in such a way as to reproduce the hormonal changes that occur during the normal menstrual cycle. This may be done in many instances by administering 1.66 mg. of estradiol benzoate intramuscularly twice a week for three weeks, although the effective dose varies in different patients. One day after the last dose, the daily administration of 10 mg. of progesterone is begun and continued for three days. Menstruation will usually set in within two to five days after the last dose of progesterone. The course of treatment may then be repeated.

In a few patients, scanty and delayed menstruation is caused by *hypothyroidism* and may be corrected by the administration of desiccated thyroid alone. Occasionally in patients with menorrhagia who are very obese, menstruation will appear at regular intervals following great loss of weight.

Primary Hypoovarianism—Substitution therapy is indicated in primary deficiencies of the ovary, notably in the menopause and in some cases of sexual immaturity. When the ovaries fail to function during the period of puberty, a syndrome develops that resembles the eunuchoid state in the male. Secondary sex characteristics do not appear, the breasts remain undeveloped, the external and internal genitalia remain infantile, little if any axillary and pubic hair appears, menstruation does not set in and skeletal disproportions are evident, the trunk being short and the extremities long although the total height of the body may be within normal limits.

TREATMENT—Following the administration of suitable dose of *female sex hormone* (from 1.66 mg. to 5 mg. of estradiol benzoate or dipropionate once or twice a week) to such a woman development of the secondary sex characteristics is noted with enlargement of the breasts, growth of the labia minora and uterus, gain in weight of from 15 to 20 pounds, increase in strength and development of a normal emotional status. Similar changes are induced by *stilbestrol*. If uterine bleeding appears at irregular intervals but may be brought to

regularly by combining the administration of estrogenic material with progesterone in the proper manner

The Menopause—The menopause is one of the major glandular problems that confront women. The symptoms vary greatly in intensity and duration, although it is not uncommon for them to last for several years. They are completely controlled by the administration of some suitable form of *female sex hormone* such as estradiol benzoate or dipropionate. The effective dose varies from 1.66 mg to 5 mg every seven to fourteen days, by intramuscular injection. The synthetic estrogen, stilbestrol, is highly effective and possesses the advantages of cheapness and of being active when administered orally. It is important to administer the minimum amount that will control symptoms. The effective dose varies from 0.33 to 1.5 mg daily in most patients.

One of the serious complications of estrogenic therapy is the production in some women of abnormal and excessive bleeding. This is most likely to occur in patients with fibroids, particularly when large amounts of estrogenic material are used. Women with fibroids must be treated with the greatest caution, and it is important in all instances not to overtreat the patient.

In the treatment of ovarian deficiencies of all types, it is essential that the patient be examined frequently and that the endocrinologist work in close cooperation with the gynecologist.

THE TESTES

The most important chronic endocrine disorders of the testes are the primary and secondary types of male hypogonadism, the secondary type being the more common. Examples of this are the Frohlich syndrome and chromophobe adenoma of the pituitary described above and also some cases of undescended testes in which the primary defect appears to lie in the anterior lobe of the pituitary. Chorionic gonadotropin is effective in the treatment of these conditions and is commonly employed in a dose of from 500 to 1000 international units three times per week.

Eunuchoidism—Eunuchoidism may be primary or secondary and is usually associated with bilateral cryptorchidism, although very small atrophic testes may be present in the scrotum. The condition is characterized by poor development of secondary sex characteristics and by certain skeletal disproportions, notably a short trunk and long extremities. Eunuchoidism may vary in degree, depending upon the amount of function of the testicular tissue. Eunuchism represents complete loss of testicular function from inflammation, trauma or total ablation of the testes.

Treatment—In some cases of eunuchoidism, stimulation therapy may be effective, although in the majority, treatment with *male sex hormone* is indicated in a dose of from 25 to 50 mg administered intra-

muscularly three times a week. Striking changes occur with this material. In sexually immature men all the secondary sex characteristics will develop, including growth of the genitalia, prostate and body hair, lowering of the pitch of the voice and development of the musculature. All of the symptoms of eunuchoidism are completely alleviated by this form of therapy. The skeletal disproportions cannot be corrected after the age of puberty.

Male Climacteric.—In a few men a condition known as the male climacteric occurs after the age of forty-five years. It is very much less common than the menopause in the female, although the symptoms are similar. It is relieved promptly by the administration of male sex hormone. Great care must be exercised in arriving at the diagnosis in order not to overlook any serious organic disease.

THE TREATMENT OF GRAVES' DISEASE WITH SEVERE EXOPHTHALMOS

WILLIAM T. SALTER, M.D., F.A.C.P.*

AND

MAYO H. SOLEY, M.D.†

HISTORICAL INTRODUCTION

ALTHOUGH its etiology has not been established, Graves' disease is regarded as a well understood syndrome by most clinicians. The easy establishment of the diagnosis coupled with the development of relatively safe methods of subtotal destruction of the thyroid by means of surgical ablation or roentgen therapy together have resulted in a routine method for handling these patients. Severe, progressive exophthalmos, a complication of Graves' disease, recently has attracted the interest of several groups of workers who believe that its presence considerably alters the immediate and subsequent treatment of the disease.

Since the first association of exophthalmos by Parry,¹ Graves² and Basedow³ with the syndrome of hyperthyroidism, the ocular signs have been considered one of the three cardinal features of Graves' disease. These early writers distinguished stare from true exophthalmos but did not explain the mechanism by which proptosis was produced. Naffziger,⁴ Ginsburg,⁵ Brain and Turnbull⁶ and Soley⁷ have reviewed the work leading to our present knowledge of the orbital changes that cause exophthalmos. Most workers agree with Naffziger⁴ that an increase in the volume of the posterior orbital tissues is responsible for the proptosis, the major change occurs in the extraocular muscles, which show marked edema, destruction of muscle fibers with loss of the usual architecture, increase in fibroblasts and round cell infiltration. The fact that these changes may be minimal or extensive explains the varying degrees of exophthalmos in Graves' disease reported by Cattell,⁸ Plummer and Wilder,⁹ Mainini,¹⁰ Soley⁷ and others.

Severe, progressive exophthalmos has been noted most often after treatment of the hyperthyroidism, although Soley¹¹ has shown that severe degrees of exophthalmos occur not infrequently during the untreated phase of Graves' disease and may require specific therapeutic

even may show simultaneously evidence both of Graves' disease and incipient myxedema, and present the appearance of a frightened cow with rough skin, protruding eyes, agitation and bovine personality (2) After long-continued Graves' disease with hyperthyroidism the thyroid gland may have suffered exhaustion atrophy (this result frequently led to myxedema in the old days as a sequel to untreated hyperthyroidism) The nervous symptoms and the exophthalmos may persist, however, long after the thyroid has petered out (3) In the idiopathic type, the thyroid gland may not participate in the Graves' disease Why the gland remains aloof we do not understand In some cases it becomes involved after many years of splendid isolation, but in other cases it never becomes involved This type of patient is the most convincing clinical evidence that the thyroid plays only a secondary role in the pathogenesis of Graves' disease

The picture presented above in its simplest terms has described two extremes, namely (a) Graves' disease with marked thyroid activity and (b) Graves' disease with normal or subnormal physiologic activity on the part of the gland In actual fact the entire population of thyroid problems presents a more complex picture All degrees of nervousness and exophthalmos may accompany any degree of metabolic turnover The skilled physician must learn to evaluate the two groups of findings *relative* to each other The dangerous situation is that combination in which the metabolism is low and the exophthalmos great!

EXOPHTHALMOS VERSUS LID RETRACTION IN EXOPHTHALMIC GOITER BEFORE AND AFTER THYROIDECTOMY

Stare must be distinguished from true exophthalmos This condition results from retraction of the upper lid which exposes a greater amount of the sclerae and on casual observation gives a false impression of exophthalmos Stare usually disappears after treatment of hyperthyroidism Whereas this satisfies the patient, it should not delude his physician into the belief that the eyes are necessarily less prominent Retraction of the upper lids draws attention to the eyes, while moderate or even severe exophthalmos may escape notice when retraction of the upper lids is absent Retraction of one upper lid frequently causes an illusion of unilateral exophthalmos when in reality the eyes are equally prominent on measurement.

True exophthalmos is recognized easily by determination of the distance from the deepest portion of the lateral wall of the bony orbit to the point of greatest convexity of the cornea and can be measured with a Hertel ophthalmometer The eyes appear uncomfortably prominent and obvious photophobia and excessive lacrimation may accompany the prolonged use of the eyes or the patient's subjective complaint of discomfort in bright light, wind or dust The conjunctivae injected The conjunctivae and sclerae may be edematous to the

point of formation of redundant, sacklike folds that may protrude at the lid margins. Periorbital edema often is present and may involve the eyebrows as well as the lids. Patients frequently complain of frontal headaches and tenderness on pressure against the globes. Impaired convergence indicates weakness of the internal recti muscles. Weakness or complete loss of function of other extraocular muscles also is seen, and in the extreme cases reported by Brain and Turnbull⁶ and others there may be complete immobilization of the globes. Weakness of the extraocular muscles may cause the patient to complain of either blurring of vision or diplopia, the muscles involved are determined by careful examination. Increased orbital resistance is demonstrated by making pressure against the eyeballs. If the symptoms and signs still leave reasonable doubt as to the presence of exophthalmos, photographs of the patient taken before the onset of Graves' disease sometimes may be obtained for valuable comparison. These supplement and verify the repeated routine observations with the Hertel ophthalmometer, which are made at each examination of the patient.

In spite of the loss of stare after treatment of hyperthyroidism, approximately 40 per cent of patients with Graves' disease will have significant progression of existing exophthalmos which becomes even worse should hypothyroidism occur. In those patients in whom exophthalmos is a presenting symptom of their disease, complications of the exophthalmos must be anticipated, especially when thyrotoxicosis has been treated. After treatment of this disease, progression of exophthalmos may be noted by both patient and physician and is accompanied by an exaggeration of the original symptoms and signs in the eyes. Diplopia may become a constant rather than a transient manifestation of eye fatigue. Orbital and scleral edema increase. Vision may be affected due to papillitis. Finally, corneal ulceration may occur.

THE PITUITARY AND ITS THYROTROPIC HORMONE

Schockaert and Foster¹³ demonstrated among the first of many investigators that extracts of the anterior lobe of the pituitary produce in ducks, goldfish, guinea pigs and several other species two major responses. These are, first, hypertrophy and *hyperplasia* of the thyroid gland leading to increased liberation of thyroxin into the blood stream under ordinary conditions, and secondly, *pronounced exophthalmos*, which may be accompanied by general edema of the orbital tissues and degeneration of the extraocular muscles.

Furthermore recent experiments with certain drugs containing sulfur have demonstrated that the natural pituitary secretion can lead to a marked increase in thyroid cellular activity. Mackenzie, Mackenzie and McCollum¹⁴ and Astwood¹⁵ have produced extremely hyperplastic thyroids in animals by administering drugs like sulfaguanidine and thiouracil. To a trained pathologist's eye, these tissues are practically

indistinguishable from the primary hyperplasia of severe Graves' disease. Nevertheless, the animals are suffering from severe hypothyroid disease, i.e., lack of thyroxin. In this case, therefore, a marked discrepancy between histological status and actual function occurs.

It can be demonstrated readily that this histological change is due to pituitary activity: first, because examination of the pituitary shows characteristic changes compatible with hypersecretion, and secondly, because if the animal's pituitary be removed, administration of the drugs fails to change the appearance of the gland. There seems to be little doubt, therefore, that the thyroid's activity is under continuous control by the pituitary and that this "thyropituitary axis" is affected by the concentration of circulating thyroid hormone, perhaps through the mediation of some hypothalamic center.

Less is known about the relation of thyrotropic secretion to exophthalmos. It is not clear why an alkaline extract of the anterior lobe should have so specific an influence upon the eyes. Marine¹⁰ has shown that this effect can be produced in the absence of the thyroid. Likewise, it can occur after removal of the upper cervical sympathetic trunk and ganglia. Its action, therefore, appears to be a direct chemical stimulation similar to the effects of estrogens upon the uterine mucosa. It has been shown both *in vitro* and *in vivo* by Seidlin¹⁷ and Rawson¹⁸ that the thyrotropic hormone of the pituitary can be removed from solution by slices of thyroid gland or by the intact thyroid. This is due to a remarkable chemical affinity between the thyrotropic hormone and its "target" gland, namely the thyroid. Presumably the eye becomes involved because the thyroid fails to remove all of the tropic hormone circulating in the blood stream. In addition, if the amount of thyroid tissue is diminished by surgery, the eyes can become more prominent because pituitary secretion probably continues at an increased rate—the so-called "castration phenomenon." In other words, normally the thyroid protects the eyes from thyrotropic hormone by removing it from the blood stream.

This assumption is further supported by the high concentrations of urinary thyrotropic secretion found in cases of Graves' disease (*a*) immediately after subtotal thyroidectomy and (*b*) in the idiopathic cases of exophthalmos. Similarly, high urinary concentrations are found in myxedematous patients in whom the gland has atrophied spontaneously. In brief, then, our present conception of exophthalmos in Graves' disease is that it is due to a chemical effect of the pituitary secretion upon orbital tissues, and that the thyroid tends to protect the eye by sopping up the pituitary substance responsible for the exophthalmos.

This statement must be regarded at present merely as a working hypothesis, but it already has stood successfully the test of repeated applications in clinical cases as well as in experimental animals. The

immediate object lesson of this concept is twofold, namely (1) that to protect the eye one must leave undisturbed the thyroid gland and (2) that one must discourage or inhibit the noxious pituitary activity.

Starr,¹⁹ among others, has demonstrated the inverse relationship between pituitary activity and thyroid activity. Further details concerning this automatic adjustment between thyroid and pituitary activities have been given by Salter²⁰ in his description of the "thyropituitary axis." From the standpoint of therapy the logical conclusion derived from this concept is that thyrotropic secretion tends to be checked by administration of thyroxin. Indeed, it must be assumed that Graves' disease *in itself* tends to be self-limiting because the greater the hyperthyroidism, the more inhibition will be applied to the pituitary. Perhaps the cyclic exacerbations and remissions characteristic of the disease are due to vacillations of some mechanism resembling a thermostat and located in the lower brain. Although unproved, this concept will afford the basis for further therapeutic approaches to this disease which includes so many psychosomatic aspects.

TYPICAL CASES

The following case history illustrates moderately severe exophthalmos in a patient with frank hyperthyroidism.

Case I. Moderately Severe Exophthalmos Following Subtotal Thyroidectomy—Mr B S L., a clerk, thirty two years old entered the University of California Hospital on Feb. 11, 1941, because of exophthalmos of two months duration. Essential features of the present illness were easy fatigability and dyspnea with exercise for one month, increased warmth, excess perspiration, diarrhea, nervousness and irritability and a lump in the neck for three to four weeks. His right eye had become more prominent during the two weeks prior to entry.

Family History: Not contributory.

Past History: He was born in Hawaii and had been in the United States for ten years. He remembered no illness or operations except for a nasal operation in 1926.

On physical examination he appeared to be a hyperkinetic Chinese who was flushed, warm and perspiring. There was bilateral exophthalmos; the right eye was more prominent than the left and showed more periorbital edema. Lid lag was present. His thyroid was enlarged. His heart was overactive with a loud mitral systolic murmur. The pulse rate was 110, blood pressure, 120 systolic and 78 diastolic. He had a fine tremor of his extended fingers. The basal metabolic rate was +38 per cent. Blood count and urine examinations were normal. Chest film was normal except for enlargement of thyroid and cardiac shadows. An electrocardiogram was normal except for sinus tachycardia. His eyes measured 17 mm. on the right and 16 mm. on the left (Fig. 4').

After the usual preoperative preparation a subtotal thyroidectomy was done on March 6, 1941 and 28.5 gm. of hyperplastic thyroid tissue were removed leaving about 60 gm. in situ. His postoperative course was uncomplicated. He gained from 131½ pounds at entry to 151½ pounds in May 1941. His basal metabolic rate was -4 per cent and plasma cholesterol was 157 mg. per cent. His eyes showed more exophthalmos, edema and diplopia and measured 21 mm. on the right and

18.5 mm on the left. He was given Armour's thyroid, and was maintained on 0.1 gm and two drops of Lugol's solution daily

By July 1941, the patient's weight had decreased to 146 pounds, diplopia was less noticeable to the patient, and his eyes measured 20.5 mm on the right and 19.5

Fig 42—Photographs of patient B S L during phase of hyperthyroidism. At the time these pictures were taken his right eye measured 17 mm and his left eye 16 mm.

mm on the left (Fig 43). On the same regimen, by August 25, 1941, his right eye measured 20.5 mm and his left eye 21 mm. Re-examination in the hospital was carried out and no important information was added, his metabolic rate was -1 per cent and plasma cholesterol 163 mg per 100 cc. By January 1942, his right

Fig 43—Photographs of B S L fifteen months after subtotal thyroidectomy. His right eye measured 20.5 mm and his left eye 20.5 mm.

eye measured a little less than 20 mm and his left 20.5 mm and on August 3, 1943, his right eye measured 19+ mm and his left eye 20— mm. His eyes were much better at this visit with only slight diplopia on looking to the extremes of right and left.

As an example of a fulminating case, the following short history is given

CASE II—Severe Exophthalmos Following Subtotal Thyroidectomy—A forty-two-year-old male married merchant consulted his physician because of nervousness. For nearly a year his eyes had been increasing in prominence so that his friends remarked about them. There had been some tendency toward tachycardia on excitement but the pulse had been found to be slow when the patient was at ease. There had been slight gain in weight during this period despite poor appetite. The patient had not minded the heat and had suffered from cold. There had been only mild sweating even in warm weather. The basal metabolic rate was found to be between +19 per cent and +14 per cent.

Examination revealed only questionable enlargement of the thyroid together with moderate exophthalmos and fine tremor of the hands. After consultation with an internist the thyroid was removed subtotally.

Within three days both eyes became markedly prominent. The sclerae became erythematous. Within a week this patient was unable to shut his swollen eyelids and marked periorbital edema was present. Purulent exudate accumulated in both eyes from which positive pneumococcus cultures were obtained. Corneal ulceration, bilateral, was demonstrated with fluorescein. An attempt to suture the lids together failed.

Ten days after the operation the everted angry red conjunctival sacs of both eyes were flush with the skin and were mistaken for mercurochrome dressings at first sight. In the center of each was a dirty spot which represented the remains of the crumpled cornea. It was impossible to distinguish between sclerae and conjunctival mucosa. The small venules about the eyelids were distended and the skin so edematous that the characteristic retrocession of the eye was obliterated. The aqueous humor had escaped on both sides and the patient was completely blind. The blood hormonal iodine taken at this time was 81 micrograms²¹ per cent, i. e., just over the upper limit of normal (80).

We are indebted to Dr. Louis P. Hastings of Hartford, Connecticut for the following *pathological report*:

Macroscopic Specimen received in formalin consists of masses of recognizable thyroid tissue marked by multiple incisions. Reconstruction does not allow accurate measurement but the total weight of tissue is 30 gm and the contour suggests a moderate enlargement of the thyroid gland. The fixed parenchyma is yellowish in color somewhat firm without grossly visible colloid.

Microscopic Multiple sections are similar showing a diffuse but varied picture. The variations run from normal thyroid parenchyma to scattered small islands of typical though mild, hyperplasia to other areas which represent typical involution. There are scattered nodules of lymphoid tissue and several areas in which the connective tissue trabeculae are thickened. The entire picture appears consistent with a moderately hyperplastic thyroid which is undergoing and has undergone involution.

Pathological Diagnosis Parenchymatous Hyperplasia with Involution

This fulminating course was obviously a rather unusual one, but entirely characteristic. The eye signs, at first only moderate in extent, immediately after operation became very severe. It should be noticed that although the nervous group of symptoms brought this man to a doctor, there was very little evidence of true hyperthyroidism as shown by increased caloric consumption. Indeed the patient had gained weight and suffered from cold. These facts are warning signals in cases of this sort. Why remove the thyroid if it is not hyperactive?

PATHOLOGICAL FINDINGS IN BIOPSIED OR AUTOPSIED CASES

Two factors influence the course of exophthalmos. Because the orbit is for practical purposes a closed space, an increase in the orbital contents necessarily results in a forward and probable downward displacement of the eyeball. If the orbit is large, obviously more space is available within it and edema of the orbital contents produces less effect than in an orbit of smaller dimensions. Venous return is more apt to be impaired within orbits of small volume. This impairment may be accompanied by rapid progression of exophthalmos with functional disturbances of the extraocular muscles, corneal ulceration, papillitis and panophthalmitis.

Fig. 44—Photomicrograph of a section of the superior rectus muscle taken during supraorbital decompression in a patient with hyperthyroidism, severe exophthalmos and bilateral corneal ulceration ($\times 300$)

The second factor is the degree of inflammatory reaction in the extraocular muscles (Fig. 44) and orbital fat. In most instances, the extraocular muscles obtained at biopsy during orbital decompression or at postmortem show evident edema. Occasionally, cases such as those having supraorbital decompression as determined by Dr. Howard C. Naffziger, or members of his staff, show relatively little edema. However, pathological techniques generally employed do not permit an accurate estimate of edema that can cause an increase of even 10 per cent or more in the size of extraocular muscles. Usually other changes such as degeneration of muscle fibers, infiltration with round cells,

especially about blood vessels and fibrosis are seen in microscopic sections. Certainly muscles seen grossly during orbital decompression are pale and several times normal size. Orbital fat varies considerably in amount among individuals, but if much fat is present in the posterior orbit, edema of this tissue may play an important part in ocular proptosis. Biopsy of orbital fat can be associated with bleeding that is difficult to control, consequently it is not often done. Only patients with orbits of large capacity that contain small amounts of fat should risk having severe exophthalmos with their Graves' disease.

THE EFFECT OF THYROID THERAPY

If the role of the pituitary in controlling thyroid activity really is regulated by the concentration of circulating thyroid hormone, it should follow logically that thyroid activity can be suppressed by increasing the concentration of thyroxin in the blood stream. Presumably this sort of automatic suppression occurs in hyperthyroidism just as it occurs in the normal individual, with the exception that in Graves disease the automatic shut-off mechanism is set at too high a point. Nevertheless, just as the malarial chill and rigor can be shortened by raising the patient's body temperature so that he becomes feverish sooner, so by increasing the patient's hyperthyroidism it should be possible to cut off the pituitary trophic activity.²² Obviously such a measure constitutes heroic therapy, because actually it is adding insult to injury as far as hyperthyroidism is concerned. Such heroic therapy, however, may occasionally be justified if vision is at stake.

When this approach is undertaken it must be done under ideal conditions. The patient must be hospitalized and kept at complete rest. Due care must be taken to maintain nutrition and especially the reserves of liver glycogen despite the increased caloric consumption. Due consideration of the risk to the patient's cardiac reserve must be paid. All such hazards must be weighed carefully by the attending physician in deciding how far thyroid therapy may be pushed. The following brief case history will illustrate the procedure.

CASE III—A thirty six year-old single male janitor complained of bilateral exophthalmos of seven months duration. Both eyes showed marked chemosis and conjunctivitis with exudate. The lower lids contained 3 mm nodules which, on biopsy, consisted of chronic inflammatory cells of the lymphoid and eosinophilic granulocyte series. There was no change in appetite nor loss of weight. The thyroid was not palpable and the skin was normal. Tremor and tachycardia were absent. The basal metabolic rate was -10 per cent. The Huedde exophthalmometer showed the cornea of each eye to be 24 mm anterior to the lateral orbital bone margins. The concentration of circulating protein-bound iodine was 11.4, i.e., 64 micrograms per cent.

In view of the patient's good physical condition and negative heart exams

tion, he was adjudged a suitable risk for increased thyroid activity. Accordingly, thyroxin therapy was given for five days, 1 mg intravenously each day. This series of injections increased the circulating protein-bound iodine to 103 micrograms per cent but the basal metabolic rate, as calculated, rose only slightly. Thereupon four more daily injections of 1 mg of thyroxin intravenously were given. At this time the recorded basal metabolic rate was -8 per cent. The patient's general condition was good but his eyes were unchanged. Accordingly more heroic therapy was undertaken after due deliberation.

On the first day 10 mg of thyroxin were injected intravenously. Because late in the second day the patient's beginning response (mild fever, muscle pains) was slight, another 10 mg intravenously were given after due deliberation. Thereafter for five days heavy sedation with barbiturates was given. At the end of this time the basal metabolic rate was +34, and the circulating hormonal iodine was 18 micrograms per cent. The conjunctivitis and periorbital edema had begun to subside.

A week later measurement of both eyes gave the values for corneal prominence as 18 mm (right eye) and 17.5 mm (left eye). By this time the nodules in the eyelids had all but disappeared and only one eye remained bloodshot. Thyroid therapy by mouth (10 grains a day) was instituted and slowly tapered off to 3 grains a day over the course of a month. The patient continued to improve remarkably, and within three months appeared normal except for moderately prominent eyes. He still had to be careful, however, not to get ashes in his eyes because of the susceptibility to irritation.

The patient continued at his job, leading a quiet secluded life and avoiding excitement, until summoned by Selective Service. He had been cautioned that undue excitement would probably cause his disease to recur. This prediction was verified after a few weeks of "hardening" at an army camp.

It must be emphasized that this approach is heroic although logical. It must be undertaken only under ideal circumstances and under skilled advice.

The risk of cardiac disability must be considered constantly and weighed against loss of vision. Absolute quiet and heavy sedation should be maintained. Successive measurements of the prominence of the eyeball should accompany repeated measurements of basal metabolic rate and of circulating protein-bound iodine. More experience is needed before the overall value of this procedure can be assessed. Obviously, it is better suited to younger vigorous individuals.

MANAGEMENT OF PATIENTS TREATMENT OF EYES INCLUDING INDICATIONS FOR SUPRAORBITAL DECOMPRESSION

The patient with severe exophthalmos and hyperthyroidism should be treated in such a way as to protect him, if possible, from further proptosis. If his thyroid is not too large (not over 50 gm) as estimated by examination and his hyperthyroidism not critical, *x-ray therapy* to the thyroid may be instituted. This method of subtotal destruction of the thyroid is a gradual one and hypothyroidism is a rare complication. The usual method is to give three courses of 900 roentgens each with six weeks between courses, the individual course consists of 150 roentgens on each of six successive days.

When the hyperthyroidism is severe and the thyroid large or nodular, *subtotal thyroidectomy* is preferred during which more thyroid tissue (5 to 8 gm) than usual is left in situ. Hypothyroidism must be watched carefully and treated early when it occurs. With either form of treatment, the patient should be kept under close observation and urged to return for care should his eyes bother him in any unusual way.

Treatment of the eyes per se involves protection from dust and irritation. Glasses with side pieces may be recommended. If there is blurring or diplopia the patient should be fitted with prism lenses. Sterile isotonic saline solutions may prove soothing. Five per cent sulfathiazole ointment may be used if there is corneal ulceration, although some patients complain of discomfort from its use. The lids may be sutured for cosmetic reasons so that less sclera is exposed or for protection of the eyes during the administration of a general anesthetic. We have seen one patient (see Case I) who had entropion that was temporarily relieved by the use of a strip of adhesive tape placed just below the lower lid margin and fastened down over his cheek so that the lower lid was everted.

In spite of a rather extensive experience at the University of California Hospital, there is no unanimity of opinion as to the indications for *supraorbital decompression*. Failing vision from papillitis and perhaps secondary optic atrophy necessitate operative intervention. Exophthalmos of such a degree that the eyes are partly open during sleep may allow drying, abrasion and ulceration of the cornea and this situation often is an indication for decompression. Extreme edema of the sclerae and conjunctivae may persist, as happened in one of our patients when decompression is postponed too long. On the other hand, a patient like that one whose history is related (Case I) may begin to have measurable recession of his eyes at a time when both attending physicians and neurosurgical consultants have decided that decompression is indicated. Only repeated examinations of a given patient and the help of the neurosurgeon will permit arrival at an adequate decision.

Supraorbital decompression as described by Naffziger is carried out through a right or left frontal approach. The dura is elevated from the orbital plate and the orbital roof is removed as widely as possible including the roof of the optic foramen in some instances. During the first three postoperative days temporary accentuation of orbital edema may obscure partially the regression of exophthalmos but later the exophthalmos may decrease 6 to 9 mm by measurement. In a few cases, there may be little or no regression. Pulsation of the globe occurs to some degree after decompression and as reported by Ginsburg,⁶ may be uncomfortable for the patient.

COMMENT AND SUMMARY

Physicians and surgeons alike have come to regard with apprehension cases of Graves' disease with severe exophthalmos.^{12 23} The actual exophthalmos must be distinguished from exposure of the eyeball due to simple retraction of the upper lid.⁷ The degree of exophthalmos can best be measured with suitable exophthalmometers resting against the lateral bony orbital margins. Even so, the evaluation of such measurements, as regards prognostic and therapeutic interpretation, depends upon certain factors, notably the shallowness of the bony orbit and its general configuration. Prolonged and progressive exophthalmos of this type leads ultimately to varicosity of the orbital veins with ensuing ecchymosis of the conjunctival sacs and marked periorbital edema. Despite local antisepsis, including sulfonamides, infection of the eye may occur and lead to corneal ulceration, loss of aqueous humor, prolapse of the iris, and ultimately panophthalmitis. One eye may be affected more than the other, and occasionally one eye may increase in prominence as the other recedes. During this process edema and degeneration of the extraocular muscles lead to partial paralysis of ocular movements (ophthalmoplegia).

Simple local measures such as antisepsis, douching and even suture of the lids are often ineffective in preventing dissolution of the visual apparatus. In cases of doubt, the experienced physician will resort to the heroic measure of orbital decompression by surgical removal of portions of the bony orbit. Before this stage is reached, however, thoughtful medical management should be instituted in the hope of avoiding a desperate situation.

In the first place, surgical removal of thyroid tissue should be avoided in those cases in which the patient, although very nervous and exophthalmic, shows little evidence of heightened metabolism. In the second place, especially in the younger vigorous individuals, the risk of producing artificially a state of marked hyperthyroidism should be weighed carefully against the anticipated inhibition of pituitary secretion with relief of eye symptoms. In so doing, general supportive measures must not be neglected. These include complete rest with sedation to protect the circulation, maintenance of nutrition with emphasis upon fluid, vitamins and carbohydrate, the judicious use of eye salves and lotions, and the protection of the eyes from external irritation or contamination by dressings and other devices so designed as not to interfere with free drainage.

On the whole, prevention and foresightedness should be the watchword in treating these cases. The physician who handles thyroid problems must bear in mind constantly the possibility of this complication. Likewise, the surgeon who specializes in thyroid operations must endeavor to sift out this minority in the preoperative population, lest he add to their temporary distress a permanent and ghastly affliction.

DIABETES MELLITUS AND PULMONARY TUBERCULOSIS

JOHN A. FOLEY, M.D., F.A.C.P.*

AND

JOHN B. ANDOSCA, M.D., F.C.C.P.†

INCIDENCE OF TUBERCULOSIS IN DIABETES

THE frequent combination of diabetes mellitus and pulmonary tuberculosis is an accepted fact of clinical medicine. In 1883 Windle⁹ reported that out of 333 diabetic cases which came to autopsy 50 per cent had active tuberculous lesions, in 1906 Nannyn⁵ found the two diseases associated in 41 per cent of cases at postmortem examination. In 1931 Banzai¹ concluded from a study of the available literature that tuberculous disease was three times as common among diabetics as among the general population. Root⁶ in 1934, after investigating the incidence of tuberculosis morbidity among 1651 diabetic patients, also confirmed Banzai's conclusions that the incidence of tuberculosis was three times as common among diabetic as among the general populace.

REASONS FOR THIS FREQUENCY

The exact cause of the high incidence of tuberculosis among diabetics has not been entirely explained. Steinback⁷ and his co-workers have furnished some experimental evidence. They found that pancreatectomized diabetic dogs were less resistant to a known dose of tubercle bacilli than a control group of healthy animals. This suggests that the increased susceptibility to tuberculosis of the diabetic dogs may be due to faulty carbohydrate metabolism.

Authorities maintain that, in spite of the decline in mortality rates from tuberculosis, the mortality from tuberculosis among diabetics is steadily increasing. It has been definitely shown that patients with poorly controlled diabetes are much more prone to develop pulmonary tuberculosis than those whose disease is well controlled. Himsworth³ showed that, in a series of 300 diabetics whose disease was well controlled, only two developed pulmonary tuberculosis.

From the Boston Sanatorium and the Department of Medicine, Boston University School of Medicine. This work was aided by the W. P. A. Hospital Research Project No. 22706.

Chief-of Staff, Boston Sanatorium. Clinical Professor of Medicine, Boston University School of Medicine. Director Fifth and Sixth Medical Services, Boston City Hospital.

† Chief Resident Physician, Boston Sanatorium. Instructor in Medicine, Boston University School of Medicine.

CLINICAL FEATURES

It is generally agreed that pulmonary tuberculosis in the diabetic usually appears suddenly and progresses quite rapidly. Such a sudden appearance of the tuberculous lesion can only be explained in one of two ways. Either the diabetic is unusually vulnerable to tuberculous infection, or the tuberculous lesion lies deep-seated in the lung and remains undetected until it rises to the surface and produces its physical signs. It is our opinion that the latter explanation, namely, the deep-seatedness of the tuberculous lesion in the diabetic, accounts for the sudden appearance of the disease as soon as it reaches the surface of the lung.

Consequently we recommend radiological examination of every diabetic's chest every six months. Clinicians report quite a discrepancy between radiological and clinical examination in diagnosing tuberculosis in the diabetic. Himsworth⁸ states that in his clinic, out of a series of 230 consecutive diabetic patients, pulmonary tuberculosis was detected by clinical means in two and suspected on clinical grounds in two others. In this same series radiological examination revealed a lesion in the lung in fifteen cases. Thus by clinical methods tuberculosis would have been detected in only 1.4 per cent of the patients, although it was actually present in 6.5 per cent.

The pulmonary tuberculosis found in the diabetic does not show any remarkable characteristic clinical symptoms or physical signs. Errors of course, are often made in ascribing these symptoms to the patient's diabetes rather than to his tuberculosis. A striking feature that was noted in the course of the diabetes in the adult was *rapid loss of weight* preceding the development of tuberculosis. Some patients had lost as much as 75 pounds in several months.

As regards the *roentgenographic examination* we have sometimes noticed the so-called tubercular-diabetic or the butterfly type of lesion. The salient features of this type may be described as a soft exudative process spreading from the region of the hilum toward the periphery most commonly in the midzone of the lung, leaving the apex and at times the extreme base free from disease.

It is the consensus that in the great majority of cases diabetes does not follow the tuberculous infection but rather tuberculosis afflicts the diabetic.

In our series of twenty-eight cases, diabetes definitely preceded the tuberculous infection in twenty-two, tuberculosis preceded the diabetes in two cases, in three cases the diagnosis of pulmonary tuberculosis and diabetes was made at the same time and we were in no position to say which condition came first.

The *age distribution* of the tuberculous diabetic patient parallels that of diabetes rather than that of tuberculosis in the general popu-

lation (Table 1) The average age in our series was forty-seven years. The oldest patient was sixty-seven and the youngest was twenty-one. The group comprised sixteen male and twelve female patients, all were of the white race except three, two of whom were colored and one Chinese.

¹ Pneumothorax.

² Pneumoclysis.

The tuberculosis which is associated with diabetes is in the great majority of cases of the far advanced type. The stage of the pulmonary disease in the entire group of twenty-eight cases classified according to the criteria adopted by the National Tuberculosis Association was as follows: minimal stage, none, moderately advanced 11, or 39 per cent, far advanced, 17, or 61 per cent (Table 2). It is in

TABLE 2—STAGE OF PULMONARY TUBERCULOSIS

	Number	Per Cent
Minimal	0	0
Moderately advanced	11	39
Far advanced	17	61

teresting to note that no case in the series could be classified as minimal. All the patients in the series had a positive sputum. We recommend sanatorium care for all diabetics with a tuberculous lesion until both conditions are stabilized and controlled.

TREATMENT OF THE COMBINED DISEASES

For the past two years it has been our policy to treat our tuberculous diabetics on a high caloric house diet of at least 3000 calories. The three main component foodstuffs are roughly in the proportion of carbohydrate 3, protein 1 and fat 1, in addition to sufficient minerals and vitamins. An example of an ordinary daily diet consists of 345 gm of carbohydrates, 120 gm of protein and 130 gm of fat, totalling about 3030 calories. This procedure has been successfully employed by Kutschera-Aichbergen⁴ (1931) and by Vrhovae⁸ (1937).

Fishberg² (1932) stated that patients submitted to a low caloric diet certainly lose their glycosuria but at the same time a rapid progress of the pulmonary tuberculosis occurs. Again, if the limitation of calories in a diabetic helps to decrease the patient's resistance to pulmonary tuberculosis, we believe that the opposite, namely, a high caloric intake, should be beneficial to a diabetic patient with tuberculosis. It was special attention to these points which led us to stress the importance of a high caloric diet supplemented by ample minerals and vitamins.

We do not advocate a high caloric diet for the tuberculous diabetic patient without strict control of his diabetes through the use of insulin. The diabetes should be brought under control as soon as possible so as to retard any further spread of the tuberculous lesion. To this end no attempt is made to build up the patient's diet from one of low to one of high caloric value, nor is any attempt made to spare the amount of insulin required to bring about control. The full high caloric diet is given as soon as the patient is admitted to the sanatorium. Fasting blood sugars in the beginning are taken weekly and later every two weeks. Our patients are given their required dose of protamine zinc insulin and a small dose of regular insulin every morning before breakfast. The practical advantage of protamine zinc insulin in treating tuberculous diabetics is its reduction of the frequency of injections. Furthermore, by its use it is possible to have a steady and constant formation of glycogen and in addition the danger of severe insulin reactions is definitely reduced.

Examinations of the urine are made on the wards daily before each meal and depending on the color reactions the following dosages of regular insulin are given: (a) green reaction, 5 units, (b) yellow reaction, 10 units, (c) olive reaction, 15 units, (d) orange reaction, 20 units. In addition, every morning urine specimen is examined for

sugar and ketone bodies by the laboratory technicians. The criteria of satisfactory control should be a urine consistently free from ketone bodies and either free of sugar or containing the smallest amount of sugar that the patient can tolerate without experiencing symptoms. We find that in the older cases a moderate hyperglycemia is harmless and excessive means to lower it are not employed.

Occasionally we find that in cases with much toxemia the patient may be unable to ingest a high caloric diet made up of so much solid food. In that case a fluid or semifluid diet is devised containing the full amount of carbohydrate, protein and fat. Later as the condition improves this diet can be slowly changed to contain the more solid foods. The same general principles that are followed in the treatment of the nondiabetic tuberculous patient are advocated for the tuberculous diabetic patient. Fresh air, rest and lack of worry are all essential. Some form of collapse therapy such as pneumothorax, phrenic nerve surgery, or thoracoplasty where indicated should be carried out.

Of course, due to the age and coexisting cardiovascular changes in many of the patients collapse therapy is definitely limited. The entire group was submitted to basal metabolic rate and electrocardiographic studies but no remarkable conclusions were derived except that patients with very active tuberculosis tended to have higher basal metabolic rate readings.

RESULTS OF TREATMENT

The results after two years of nutritional studies have for the most part been very encouraging. Practically every patient showed a weight gain and a definite improvement in his sugar tolerance. It was noted that the average weight gain in the eleven cases classed as moderately advanced was 26 pounds while the average weight gain in the seventeen far advanced cases was 5 pounds. The sputum became negative for tubercle bacilli in thirteen cases (47 per cent).

Out of the group of twenty-eight patients fourteen are still in the sanatorium and doing well, eight are dead and six have been discharged (Table 3). It is interesting to observe that all the patients

TABLE 3—PRESENT STATUS OF PATIENTS

	Number	Per Cent
In Sanatorium	14	50
Dead	8	28
Discharged	6	22

who died had far advanced tuberculosis while those who were discharged had moderately advanced disease. In one case which came to

autopsy the patient was found to have a bronchogenic carcinoma in addition to diabetes and pulmonary tuberculosis

CONCLUSIONS

At one time the combination of diabetes and pulmonary tuberculosis was considered fatal. The advent of insulin has certainly altered this prognosis. It is interesting to note that the tuberculosis death rate among diabetics per 1000 fell from 11 prior to the use of insulin to 4 after the use of insulin.

It is safe to say that in the sanatorium a well-controlled diabetic with tuberculosis is no more difficult to treat than a person suffering from tuberculosis alone. Early diagnosis of the tuberculous infection is the all-important factor, for, once tuberculosis has reached an advanced stage, the prognosis is poor even when the diabetes is controlled. The surest and quickest method of detecting pulmonary tuberculosis in the diabetic is by routine radiological examination of the chest every six months.

At the present time, earlier diagnosis, proper use of the high caloric diet, insulin administration and collapse therapy have all contributed in prolonging the life of the tubercular diabetic.

SUMMARY

- 1 A two-year nutritional study of twenty-eight patients with co-existing diabetes and pulmonary tuberculosis was made.
- 2 The composition of the average diet for the entire group yielded at least 3000 calories. The three main foods were roughly in the proportion of carbohydrate 3, protein 1 and fat 1.
- 3 The diabetes was controlled as soon as possible by the use of protamine zinc insulin and regular insulin.
- 4 Frequent blood sugar estimation and urine examinations are essential.
- 5 The pulmonary tuberculosis was classified as moderately advanced in eleven and as far advanced in seventeen patients. No case could be classified as minimal.
- 6 The average age in the twenty-eight cases being forty-seven years, collapse therapy was somewhat limited.
- 7 A weight gain and improvement in sugar tolerance were observed in a great number of the patients.
- 8 Of the twenty-eight patients, fourteen are still in the sanatorium and doing well, eight are dead and six have been discharged.
- 9 A poor prognosis is invariably given in the case of a diabetic with far advanced tuberculosis even if the diabetes is controlled.
- 10 The importance of early diagnosis of the tuberculous lesion, a high caloric diet and careful control of the diabetes cannot be over-emphasized.

THE TREATMENT OF GONORRHEA UNDER EXISTING CONDITIONS

P S PELOUZE, M D *

So far as the therapy of gonococcal infections is concerned, history has been so busy repeating itself that no sooner did we awaken from one dream state than we were plunged into another seemingly more beautiful. For years out of mind this was a regular experience for the medical profession. The "new treatment" only had to be more easily carried out than the last one to gather its followers who stayed on the merry-go-round grasping for the brass-ring until it slowly disappeared that, so far as results were concerned, the brass-rings were all pretty much alike. Of course, if one ring had a little more of the bizarre to it than its predecessors more physicians made a grab for it and, seemingly, they cherished it longer.

Thus, methods of treatment that had real things to offer frequently were thrown aside because they were "just too much trouble," they were used so poorly that their results were not impressive. Little time was spent in studying the disease itself and, as often as not, treatment was carried out on an I-hope-for-a-miracle basis when there were no miracles to be had.

All of this was bad enough when the physician alone held the therapeutic reins for those who consulted him, and his sole sources of information were the medical meeting, the medical press and his own clinical observations. But when the age of gonorrhea miracles did come along and the lay press became courageous enough to mention the name of the disease, the physician no longer was head-man in the picture. Patients rarely asked for information from him—they gave it. There was ushered in the era of tablet-worship and, more often than not, the physician, in those places where the druggist did not take over, became merely the dispensers of the miracle-tablets.

TODAY'S MIRACLE "CURES"

Sulfathiazole—It got noised around that 80 per cent of the gonococcal infections could be cured in five days by the use of sulfathiazole. It even was said in the *Readers Digest* that, with a bit of cooking, 99 per cent of the patients could be quickly and safely cured. Doctors believed the first and the laity credited the second just because the medical interpreter Mr. De Kruiff said it. Then, time and a world disappointment showed the medical profession that the first was

* Assistant Professor of Urology, University of Pennsylvania, Special Consultant, U S Public Health Service

so, just as they have shown many a saddened lay victim that Mr De Kruiff could be in error at times and that this was one of the times

Penicillin—Now penicillin has entered the picture of gonorrheal therapy and introduced a super-miracle age which beyond question could be the answer to the prayers of both the maiden and her boy friend. There is at present every reason to believe that under proper dosage one course of penicillin treatment will cure around 97 per cent of the patients and that a repeat course of perhaps higher dosage usually will cure the few failures on the first. Science truly has mastered the disease but—and it is rather a large *but*. There is too much gonorrhea for the too little penicillin and the wonder-drug is good for so many things beside gonorrhea—diseases that carry mortality rates—that there will have to be far more than there now is for the poor old gonorrheic to get much of it after it is proved so good for him.

Also, the present administration of penicillin is a matter of intravenous or intramuscular injection at two or three-hour intervals for twenty-four hours or more. So it is a hospital procedure that hardly lends itself to either office or clinic practice. It is going to take many beds to treat all gonorrheal patients with penicillin.

The general availability of penicillin apparently is rather well removed from the present, and even were it to become quickly available commercially it is probable that few gonorrheics could pay its cost or that few health agencies could or would pay it for them. Until all of these things are cured for we shall have to confine ourselves largely to being deeply thrilled over what science has accomplished and then get realistic and make the best use we can of the other things.

Pyrotherapy—Immediately pyrotherapy comes to mind. It, too, has been lauded almost to the sky as a means of curing our sulfonamide failures. Unquestionably it is a great addition to our curative efforts even if it is not quite so effective as generally used, as we have been led to believe. One is safe in saying that properly used it will cure or promote cure in by far the large majority of those whom sulfonamides do not cure. Its lack of availability in almost all small cities and towns and even in some of the larger ones puts it beyond the physical and, probably, financial reach of at least 90 per cent of the gonorrheics in civilian circles. So for a long time to come most physicians and their patients will have to view it from a distance.

A PRACTICAL APPROACH IS NEEDED

Thus, after rather a long dissertation and some unfortunate eliminations we, at last, have arrived at the physician's office and the usual clinic and just how they can handle the problem with today's armamentarium until tomorrow makes more generally available those other things. There will be a lot of gonorrhea to treat in that rather uncertain meantime, and it will not be cured by the dreams of better days.

to come. It will be cured because we intelligently use the things we have at hand and make ourselves mean more in the general picture than just the means by which our patients can get their sulfonamide tablets. And we will do a far better job at it if we start by gaining a better knowledge of the underlying principles of gonococcal infections than now is generally held.

SULFONAMIDE-PRODUCED ASYMPTOMATIC STATES VERSUS CURE

Before going into treatment methods it is of extreme importance that we realize that there is an unfortunate difference between sulfonamide-produced asymptomatic states and real *cure* and that difference can rather safely be placed at around 25 per cent. In other words, about that number of patients who are rendered asymptomatic by sulfathiazole are still gonococcus carriers and can transmit the disease to others. And, what with the thousands of patients who treat themselves with tablets obtained from druggists or physicians, and those who are dismissed as cured just because their symptoms are gone, one does not have to be a prophet to be able to predict the greatest epidemic of gonorrhea that our country has ever seen. We are in it now and there is far worse to come.

Without discussing pros and cons at length, some facts about this asymptomatic carrier state should be noted.

- 1 One of our large naval hospitals cultured gonococci from 23 per cent of their *males* who had been rendered symptom-free by one course of sulfathiazole tablets.

- 2 Mathis and Koch (Venereal Disease Information, Feb., 1944) obtained positive cultures in 32 per cent of a mixed group (male and female) rendered symptom-free by one course of sulfathiazole.

- 3 In this latter group 47 per cent had reached a persistently culture-negative state in one month after the positive culture, by the end of the second month 34 per cent more had become negative, by the end of the third month 14 per cent more had cleared culturally and 5 per cent were still positive after that.

Certainly, in these two experiences, and others that could be cited, one can find neither justification nor safety in the casual assumptions of "cure" based on disappearance of symptoms that so commonly return infected patients to their former pursuits to infect those who lend or sell their favors. He who weighs the matter in war and social values cannot escape a deep concern for the future.

WHAT CAN WE DO ABOUT IT?

There is some of our present grief, and just what can we do about it? We are in a wonder-age of medicine and we do not have to throw up our hands and answer, "Nothing." We can do a great deal about it if we will. We can make the best use of sulfathiazole possible and

where we have access to cultures we can use them—good cultures of properly secured materials will reveal by far the large majority of the asymptomatic gonococcus carriers. A few will escape detection by the usually advised three cultures. Where cultures are not available, one is thrown back on his clinical sense, and, by and large, whether he has cultures available or not, he might realize that neither he nor anyone else knows just when any patient is cured by these drugs. Therefore, he should be honest with his patients and himself and say so. Men do not want to transmit gonorrhea nor do many women above the prostitute or near-prostitute level. If told they may be running a grave risk of doing so if they have unprotected sexual intercourse during the first four months after the disappearance of symptoms, some will refrain and more of them will use condoms. In either

place in the scheme of things than just a means whereby the miracle-drugs could be obtained. And, believe it or not, patients actually went on to cure in that therapeutically dark age upon which the curtain was so summarily drawn about six short years ago. We even used local treatments during those days, as most of us seem to have forgotten. And some of us who used them gently and with good sense knew that they really promoted the patient's curative effort just as surely as we knew that those who used them roughly and unintelligently caused a great many needless complications and greatly prolonged the duration of infection. We didn't know the true mechanism of our stimulation of curative effort any more than did those who made applications to mucous membranes remote from the urogenital tract. We just knew it happened as did those who treated and still treat locally other mucous membranes.

Some of us were so stupid, or otherwise, that even when the rest of the world almost made them taboo we used them along with our miracle-drugs and some of us held off a little but resorted to them just as soon as there was the slightest evidence that the patient was not responding to these drugs. Not only this, but I have been told by many urologists that their disappointments had been so many that they are now using local treatment on all their males with gonorrhea and viewing sulfathiazole as a highly valuable adjunct thereto.

Evidently our urologists do not wholeheartedly agree with Berry (Urol and Cutan Review, Dec 1943, p 675) who summarily dismisses the matter with the statement, "Local treatment of the urethra is unsound in theory and unsafe in practice." After over thirty years of observation and gentle local treatment of gonorrheal urethras, I find myself more interested in results than in theory, and when I see such sweeping statements as the above I get the unkind feeling that things would be nearer truth if they read, "Any local treatments to the urethra are a nuisance for the physician and roughly carried out ones are a menace to the patient."

In other words, I strongly favor the gentle, sensible local treatment and abhor the others. I refuse to take the position that he who fails of response to sulfonamides and for whom neither pyrotherapy nor penicillin is available must sit around unaided by his physician until God in his mercy lets him get well by virtue of his own native curative responses, whether he be man or woman. It is too long a wait and too great a war and social menace.

Fortunately, for the present discussion, I am out of practice for the duration. This relieves me from all possible suspicion that the things I am about to advise are suggested because of their possible greater financial return. I have no financial interest in them. My sole interest is in the gonorrheic and his environment.

Why Local Treatment Is Desirable.—For the patients mentioned in

the immediately preceding paragraph, I am going to advise gentle local treatment whether they respond clinically to sulfonamides or not. Most of my reasons for so doing have been covered herein but, to avoid misunderstanding, I shall repeat them and add a few others.

1 There is a failure rate from the use of sulfathiazole that runs anywhere from 20 to over 50 per cent under varying conditions

2 There is an asymptomatic gonococcus carrier rate in those whose symptoms are banished by sulfathiazole that it seems reasonably safe to place somewhere around 25 per cent.

3 Gonorrhea has always been one of the greatest causes of lost-man-days among military personnel—and there is a war on

4 There are no universally available proofs of cure, and even with the best of them mistakes occur

5 Patients who become asymptomatic are often most casually dismissed, or dismiss themselves, as "cured" despite the above mentioned carrier rate

6 Even though the patient does not respond to sulfathiazole medication he seldom has the stormy disease course so common before its use in this disease. There is far less tendency for disease progression to other structures and of complications of gravity (In this statement I am considering the disease course in gently treated, co-operative patients and not disease course as influenced by rough treatment and poor patient conduct. Even in the presence of these latter factors he seldom reacts as he did in the old presulfonamide days.)

7 Treatment is sought earlier, more patients are seen in the anterior urethral stage, and most of them fail to have a posterior urethral extension if they immediately are placed upon sulfathiazole

8 Of all gonorrheal areas the anterior urethra is most easily and safely treated and if roughness of procedure and high fluid pressures are avoided no complications will be caused by it.

9 More care and judgment are required for the treatment of posterior urethral involvement with its concomitant prostatic infection, but even this is not beyond the intelligence and skill of the physician who knows that high fluid pressures spread disease and trauma to even the subacutely inflamed prostate gland does far more harm than good. There is a right and a wrong way and often a right and wrong time for most treatment procedures and it is here that the wrong way and time not only may produce irreparable harm to the patient but will and has discredited valuable procedures

10 And, perhaps most important for the day local treatment with the patient understanding how grossly the disappearance of symptoms may deceive makes the doctor king and not the tablet. Properly presented to the patients it often assures a reasonable period of post-sulfonamide observation. It will hasten the cure of the drug failure

as it unquestionably will shorten carrier states Above all things, it will protect society and it will add much to the credit of our profession

A PRACTICAL PLAN OF MANAGEMENT

The decks being cleared, so far as my personal opinions are concerned, here is what I should do if I were to return to practice today I should give the admirable Army directive for the treatment of gonorrhea in males a decided twist or, perhaps more correctly speaking, I should use the two plans suggested for anterior urethritis together rather than wait until the patient devoted from five to fifteen days in proving that he had to be classed as a "drug-failure" I should take the time to make my patient understand just what the present situation is, in order to overcome the ideas the lay press or his friends have instilled into his mind, and I would show him how easily he might become a menace to womankind In other words, I should try to shift his mind from tablets to the value of local treatment, from symptoms to the nearest to safety now obtainable for this particular group of patients

And now, having perhaps overworked the "I should" idea, it might be well, for purposes of brevity, to resort to an outline of suggested measures, with parenthetical side remarks where they seem to be needed for clarity

Anterior Urethritis—1 Make a diagnosis by demonstrating the gonococcus by either the Gram stain or culture (Approximately 30 per cent of the patients presenting themselves for urethral discharge have a nonspecific urethritis and not gonorrhea If for any reason the laboratory findings have to be delayed, treat as though it were gonorrhea until proved otherwise)

2 Inject into the anterior urethra *not more than 6 cc* of either a 5 per cent mild protein silver or a 0.5 per cent strong protein silver solution and have it retained for five minutes If sulfathiazole does not check discharge give these treatments daily until the discharge stops, and every other day thereafter for two weeks longer If sulfathiazole does banish symptoms, give daily treatments for two weeks and on alternate days for at least two weeks thereafter (The capacity of the average urethra is 10 cc The injection of fluids through an infected anterior urethra into an uninfected posterior one will precipitate many unnecessary posterior extensions of infection The constant daily use of chemicals in the urethra often will cause a continuation of discharge after gonorrhea is cured If patients cannot be seen daily give them a 1/8-ounce syringe or mark another syringe at the 6-cc point and let them use preferably strong protein silver because of its lesser staining propensities If the quantity does not exceed 6 cc he can do himself no harm with it.)

3 Prescribe 40 tablets of sulfathiazole and have him take 2 of them by mouth four times a day

4 After the five days of this medication, stop it for from three to five days and then give him a second course of 4 gm a day for five days, no matter how he may or may not have responded symptomatically (The asymptomatic gonococcus carrier rates previously mentioned were in patients responding clinically to only one such course of sulfathiazole.)

5 If symptoms persist after the second course of medication, forget the sulfonamides and rely upon local treatment (Do not, however, forget that indulgence in alcohol, sex excitation or sexual intercourse can be a cause of sulfonamide failure just as it can prevent nonsulfonamide-treated patients from developing their native curative responses. For which reason, blame irregularity of disease course on patient's behavior and you will be correct almost every time)

6 After the above program has been followed for anterior urethritis start to search for gonococci in the urinary sediment either by "smear" or culture and no matter how often the answer is negative, advise against unprotected sexual intercourse for at least three months—four months would be safer (It is true that most patients will not follow the advice to the letter but, if accidents do occur, they are not the fault of the physician. Patients who are assured they are well do not take it kindly if they later infect their wives or sweethearts. At least one such patient murdered his doctor.)

Posterior Urethritis.—The treatment of gonorrhea that has extended into the posterior urethra is not such a simple matter as when the infection is confined to the anterior urethra alone. It is here that ill-advised local treatments do most harm and, unless the physician is familiar with or will take the trouble to familiarize himself with the anatomy, particularly the vagaries of the external sphincter, the general behavior of gonococcal infections in this region and the ease with which local treatment can produce pathology that the gonococcus could not cause alone he had far better leave the whole affair to the patient's own curative responses. Time is not gained by insulting gonorrhea in this area by a lot of traumatic treatment such as high pressure intravesical irrigations and too early and too vigorous prostatic massage.

On the other hand he who knows what can be done when it can be done safely, as well as how to do it, can promote Nature's efforts to such an extent that the duration of gonorrhea from this point on can be cut in half.

All experienced physicians agree that no local manipulative measures of any type should be employed during the acute stage of posterior urethritis. They advise hot sitz baths and perhaps mild seda-

tives for the partial control of vesical irritability Most of them insist that no local treatments should be resorted to until at least a week after complete vesical comfort has been regained (One should not let this matter hinge entirely upon the presence of bladder irritability Some patients with new posterior infections, though both glasses of urine are cloudy, are perfectly comfortable Most of these, however, soon will develop the most atrocious vesical symptoms if intravesical irrigations are resorted to)

Hydrostatic intravesical irrigations, as commonly employed, have been subjected to much just criticism and many have insisted that they be not used Yet, many who condemn their use by others use them in their own offices to great benefit. Which, of course, means that, properly used, they are of definite value and improperly used they are a menace to the patient The dangers come from too great fluid pressure and completely filling the bladder even under otherwise safe pressures He who employs more than $3\frac{1}{2}$ feet of fluid pressure or completely fills the bladder at even that pressure can expect a high incidence of epididymitis He who uses catheters or Keyes-Ultzman syringes for the introduction of fluids into the bladders of gonorrheal patients should expect this and other complications

The safe introduction of 1 7000 potassium permanganate solution into the bladder every second or third day unquestionably will hasten the time when one safely may approach the digital promotion of drainage of the prostate gland He may reduce Nature's time at this stage by half but he gains no time if he introduces other complications And he who is unskilled or too impatient to wait for cut-off muscle relaxation but persists in forcing it, had far better leave the job to Nature's good offices

Whether one resorts to irrigations or not, the steady trend of such infections, *in cooperative patients*, is toward disease quiescence with its gradual disappearance of objective and, generally, subjective symptoms The second glass of voided urine becomes clear and the first glass more slowly follows suit

Residual Infection in the Prostate Gland—Sooner or later there arises the question of what to do about the residual infection in the prostate gland, and when to do it The aforementioned Army Directive states that, "The second glass of urine should be clear for three weeks and the first glass practically so before gentle prostatic massage is started" This is rather dogmatic for a disease that so often shows exceptions and, though I was a party to writing the directive, I feel one should be a little more specific regarding the matter So much needless pathology has been produced by too early and, often, too vigorous prostatic manipulations that there are many who have become unalterably opposed to their employment. I, personally, have

encountered so much of it I most certainly agree that the physician who cannot keep his mind on the end of his finger when it is in the rectum had better not put it there. He who cannot respect diseased tissue and realize that trauma should play no part in the treatment of this disease had better spend his time inspecting latrines, if he happens to be in the Services.

What is the value of the digital promotion of drainage to the prostate gland when properly carried out? Left to herself, Nature will take from three to four months to eradicate the gonococcus and aided by proper drainage promotion she usually will get rid of gonococci (if the prostate is the sole residual focus) in six or seven weeks. There will still be pus in the secretion but the gonococcus will be gone and, if there was not a focal infective prostatitis present before the gonorrhea was contracted, the pus cells will promptly disappear on further treatment. In the Services interest in the case appropriately stops when the gonococcus is gone. If they treated prostates solely because they harbored pus, just about one third of their personnel would need treatment and the war would have to stop or materially slow down. In civilian practice interest goes beyond the disappearance of the gonococcus.

Probably the safest view to take about the starting of so-called *prostatic massage* is that no one knows just when it is safe in any patient. We do know, however, that if done too early or too vigorously there will be a recurrence of urethral discharge and more or less clouding of the urine the next day and that we can use this as an indicator. If we confine our first prostatic manipulation solely to gentle pressure on the lateral lobes of the gland and there is a recurrence of symptoms we do not touch the gland again for a week. Thus we will avoid harming the patient. If after the next similar procedure there is no recurrence of symptoms, we can repeat it in three or four days and if this produces no reaction we are in all probability safe thereafter to carry out *gentle* prostatic stroking twice a week, which in my observation at least is better than treatments otherwise spaced.

When it is possible safely to carry out "massage" so as to obtain prostatic secretion for microscopic study the number of pus cells in the fresh secretion under the high dry lens should be counted. If at the end of six weeks of treatment this count has not reduced by about two thirds it is safe to say that the patient had a focal infective prostatitis before he acquired his gonorrhea. If this is to be cleared up it only can be done after the causal infections, usually tooth root abscesses, infected gum pockets or less often, infected tonsils, have received attention. To go on massaging such glands without attention to these causal foci is a waste of time, effort and the patient's funds.

Patients who have been carried through this regimen seldom carry the gonococcus unless there has been an infection of Cowper's glands or the seminal vesicles. Both of these are decidedly rare in patients who have not been subjected to high fluid pressures. The former almost invariably develop a very scanty urethral discharge lasting about two days in which the gonococcus is easily revealed following indulgence in alcoholic beverages or prolonged sexual excitation, and the latter have a profuse discharge containing the gonococcus after each involuntary sexual orgasm. All the older tests of cure again assume a value not holding for some time after sulfathiazole administration.

Where cultures are available, they, of course, should be used. In their absence microscopic studies of the washed urinary sediment of the first half ounce of urine passed immediately after digital stripping of the prostate, Cowper's glands, the seminal vesicles and anterior urethra are almost of equal value. And, no matter if all findings are negative, the physician is safest if he advises against unprotected sexual intercourse for the next three months. He does best to realize that gonorrhea is a disease of exceptions and that no matter what rules are laid down regarding it exceptions seem to occur.

SYMPOSIUM ON PSYCHOSOMATIC MEDICINE

A CLINICAL DESCRIPTION OF PSYCHOSOMATIC MEDICINE

LELAND E. HINSIE, M.D.*

I THE PROBLEM

LIVING as a human being often takes more energy than the daily tasks that gain us a livelihood. It is easier to get settled in an occupation than it is to adjust ourselves to the personal side of people. It is one of the peculiarities of man that when his energies cannot be essentially externalized, they dam up within him, within his mind or body or both. The persistent damming up leads to tension and symptoms. When the symptoms are in the mental sphere, they give rise to special names, such as psychosis and psychoneurosis. When the tensions of living localize themselves in different parts of the body, it appears that the organic part involved is the seat of the trouble—that is, the organ appears "diseased." In a broad sense of the word it is diseased—it is deprived of ease—it is disordered functionally, but the trouble stems from unhappy adjustment to life and not from such organic sources as bacteria, injury, etc.

From time to time the physician is baffled by the failure of a patient to respond favorably to a course of therapy that ordinarily brings about recovery. The patient, for instance, when first seen gave a clear-cut history of a peptic ulcer, the physical findings supported the history. The course of therapy was clear and the patient sincerely followed all instructions. Yet, after a few months of careful cooperation the symptoms are essentially unchanged. The doctor is genuinely puzzled; he surveys the entire situation again, everything is correct—diet, rest, medication; the patient has meticulously followed all. Maybe consultation with a surgeon is in order. It is held. Nothing new develops.

* Professor of Psychiatry, College of Physicians and Surgeons, Columbia University. Assistant Director, New York State Psychiatric Institute and Hospital.

The patient's general condition grows worse. The symptoms are now such that she spends a long time in bed, lately her husband has had to prepare his own breakfast, for his wife is too weak to get up. More recently he has had to prepare lunch and dinner, he has had to do the marketing. He has also had to do the housecleaning. She cannot eat at the table with him because the sight of food is nauseating.

The couple do not invite company any longer because of the wife's condition. And, besides, the wife is getting irritable. The children are neglected, they too are changing for the worse because now neither parent can give them attention.

Surprising, says the doctor. Something is wrong. A peptic ulcer should not disrupt everything in the household, should not fray the dispositions of all members to the point at which the household should be dissolved.

Somatic medicine, so to speak, has fallen far short of a cure. All the doctor's skillful prescriptions, the ones that have helped so many other patients with a similar condition, have been without avail. The ulcer does not heal.

On his next visit the doctor, knowing that a repetition of the hackneyed examination that he has so often performed would be without results, begins to ask the patient how she feels as a person, as a human being who is trying to get something out of life. The patient is surprised at such a topic of inquiry. What have her life efforts got to do with a peptic ulcer? Still, she senses that, even if the subject is irrelevant, here is the first person in her life to ask her how "she" feels. Up until this time she has been a peptic ulcer. The strangeness of her situation in life begins to dawn upon her. That's right, she thinks, I've become a peptic ulcer.

"Doctor, maybe that isn't so surprising. I'm suddenly overwhelmed with a composite picture of my past. I never was what I wanted to be. If I'm a peptic ulcer now, I was something else then, yet, it all adds up to the same thing, a disappointed and frustrated life, one always devoted to the needs and demands of others. Maybe it sounds odd, but I was not I. From my earliest years I was known as the 'little mother' around our house. I was pleased with my role as a housewife, for it occasioned considerable approbation, still, I yearned for the fun and freedom of a child.

"Mother was kind in her strictness. I didn't know it then, though later I realized what a sacrifice she was to life and living. She lived only for father and me and the house. What am I talking about, doctor? That's been my life, too.

"When I came into adolescence, I often thought overtly of breaking away. I knew I wasn't living. I was an automaton. Capable in school. I solved scholarship without trouble. But, I couldn't solve human relationships. The girls in my classes seemed to admire me, I

helped them with their school work. Outside of classes, though, I was alone. Girls of my age seemed to pity me in a way, pity from a distance, no closeness, no nearness. It's what I said a little while ago—nobody ever asked about me, about how I felt. They asked about my mathematics or languages or geography. The only difference today is that they ask about my peptic ulcer.

"While in high school I decided to become a career woman. I remember feeling heroic about the choice, a sort of heroism stemming from resignation. If I couldn't be a human being, I could be some kind of an efficiency expert, detached, cold but capable. I grew into so-called maturity with scholastic ability but beneath it all I didn't like it. It was a screen against the expression of human qualities and an effective, though a harmful screen. Over the years I grew tense, critical, misanthropic. With grim humor I labeled myself a success.

"Then a man came along. He was kind. He said he liked my type because he too placed his profession above all. We talked of love. We never quoted ourselves, our feelings about love. We quoted the literature, letting it be half-known that it was from the literature, hoping that it would appear to come from our own hearts. It was beautiful, even though it was impersonal. Love doesn't thrive with a mouth-piece. We knew that, for we talked about it at length.

"Tension, more tension. The nature in me yearned for expression. I fed it on scholarship. I was tense inside, in fact, I felt the discomfort mainly in the stomach—it felt as if it were knotted up. I lost the zest for eating, lost weight, felt weak. It was just as if my feelings went to my stomach and couldn't get any further.

"But, this is all so foreign to the cause for your calling on me. Yet is it? I seem to have gotten back to my stomach, but this time by a different route."

For the first time since he had been called in to treat her, the doctor noticed how animated she was and how relaxed as if a great burden had been lifted from her. After a pause, he gave a sort of a simple lecture. Parts of the body—the stomach, for instance, can be upset from one or more of several causes: he mentioned dietary indiscretions, bacterial troubles, chemical changes, anatomical anomalies, deficient blood supply, altered nerve activity and disordered emotions. He said that careful examinations in her case had ruled out all save the last and she had made out a clear case for the last.

The doctor cited from his clinical experiences to show how emotions can be bound to any organ of the body, whether that organ is organically sound or disordered. He showed how sick organs, particularly those belonging to the vegetative system, can be prevented from healing when the patient's emotions flood the organs. Today the term *hypochondriasis* is a household phrase meaning an "imaginary" physical ailment. It is 'imaginary,' however, only in the sense that the or-

gans are not disordered in the way that the patient believes them to be. The term pathology is enlarged to include abnormal emotions. Hence, it is said that the organ shows psychopathology. Within recent years this point of view has been subsumed under the general heading Psychosomatic Medicine.

Every disorder of the physique is represented to a greater or lesser extent in the mind of the patient. In many instances the mind plays an excessive role, so to speak. In other instances the mind plays the exclusive role, as it does, for example, in conversion hysteria. In the latter case there is usually a well-recognized "gain through illness." The youngster develops a headache just before leaving for school, the connection may not be seen, but there is a test in mathematics that morning. Or, the young lady, who does not like the pressure brought upon her by a suitor, wards him off with alleged physical complaints. Or, the wife, finding married life incompatible, becomes "a chronic invalid." Or, the laborer, unwilling to work steadily, seizes upon the gain through illness and becomes a prolonged compensation case. Or, the soldier, fearful of death, develops paralysis so that he cannot participate in battle.

Over several therapeutic sessions the doctor put the foregoing thoughts in the mind of his peptic ulcer patient. She talked at length to him.

"I became his fiancée. I wasn't at all prepared to share feelings with another, because I had trained myself almost entirely along intellectual lines. The courtship was beautiful, founded as it was on amorous quotations from several sources, but not from us. Still, I was happy in an illusory way. Not altogether so, however, because I had found myself in the business world. I was doing a better job than the man I replaced. Often I shuddered, though, when I realized I was a better man than a woman. My fine clothes were a pretense. But, the woman in me never gave me rest. It beset me from many sides. I grew tense. My appetite was poor, my stomach was usually upset. I even guessed that the woman in me was being dammed up in the stomach. My friends knew it, without realizing that they knew it, for they often told me that I was all work and no play, that I should affiliate my interests with men, in short, that I be a human being as well as an efficiency expert.

"We married. I only knew intellectually how to be a wife. My husband was little better. He was a scholar above all. Our social contacts were based on intellectuality. When we had a couple at the house for an evening of bridge, that's all we got out of the evening, bridge. Our vacations were itineraries, devoid of human interest, full of intelligence. Quiet evenings at home were supported by heavy literature.

"How I hid myself from myself! Whatever feelings I let loose came out vicariously in words. It was a terrific conflict that griped me, griped my stomach. That's just where I felt it, in my stomach. My

stomach was the stopping place for my emotions I'm sure I made my stomach sick, so that it couldn't work properly. If I clenched my fist violently for a long time I'm certain it would alter the blood supply to the hand, it would lead to skin changes, like little ulcers. Feelings can lead to ulcers, for do they not cause tensions, constrictions? All the x-rays showed spasticity.

"As the months of married life went by, I secretly wished to get away from it all. I saw my husband less and less of the time, because, as we incorrectly assumed, he was building up a professional career and was busy day and night. In one respect I was like a single woman again. But I didn't want that either. Conflict! Stomach! Ulcer!"

The patient steadily improved. After each psychotherapeutic session she could feel the release of tension in the stomach area. Now the routine physical treatments could act favorably. Gradually the peptic ulcer disappeared. Psychotherapy continued, however, for a longer period, until such time as their lives could be rearranged to the point where both husband and wife were human beings as well as machines.

The treatment was psychosomatic. We may not know how emotions get crowded into an organ or an organic system, but we know they do, and we know how destructive the results can be. The proof to date is established pragmatically: for, with the release of tensions associated with habits of living, symptoms disappear. How often have we seen the symptoms of appendicitis continue long after the appendix has been removed years longer! We've seen those same symptoms removed by psychotherapy.

It seems odd in a way that one's position in life can change one's physiology and lead to organic pathology. Yet, we know that deep grief, for example, may lead to anorexia, insomnia, inertia—all of which if of sufficient duration can produce marked physical changes.

This is the type of psychosomatic medicine that any physician can and should practice. It is simple and usually effective. Be a good listener, not alone to the body, but to the human being who has the body.

In the majority of instances, you do not have to be a psychiatric specialist though a little more formal knowledge of the whims of emotions would add considerably to the comfort of your patients.

To what sources should the physician go to get enough psychiatric background to grasp the practical application of concepts in psychosomatic medicine? The literature is beginning to be extensive yet the principles as they are known today are presented in a simple and clear manner by Weiss and English in "Psychosomatic Medicine" (W. B. Saunders Company, Philadelphia and London 1943) the subtitle of which is "The Clinical Application of Psychopathology to General Medical Problems." The title may sound a little formidable. It should not for it is only an abbreviation for what has been known in clinical

practice for centuries Psychosomatic means "relating to the mind and body" It incorporates the age-old concept that sickness affects the person and the person affects the sickness Physicians should not shy from the subject with the unwarranted belief that psychosomatic medicine is something new and untried and that, therefore, they will wait until its real, practical application to the patient is established It is an established practice All the great clinicians of the past stressed it

The scientific approach to psychosomatic medicine has been greatly facilitated by advances in organic and mental medicine The epochal researches of Freud give the physician of today a workable, scientific form of psychotherapy, one that can be used by any physician To be sure, the technic of psychoanalysis can be applied in its highest form only by those who are highly trained, yet its principles can be adequately used by any physician, particularly in that large group of patients to whom the term *psychosomatic* is directed

Weiss and English repeat the opinion of many when they say that "between the small number of obviously psychotic persons whom a physician sees and the larger number of patients who are sick solely because of physical disease, are a vast number of patients who are not 'out of their minds' and yet who *do not have any definite bodily disease to account for their illness* Psychosomatic medicine is chiefly concerned with them (Group I) It is reliably estimated that about *a third* of the patients who consult a physician fall into this group These are the so-called purely 'functional' problems of medical practice

"Approximately *another third* of the patients who consult a physician have symptoms that are *in part dependent upon emotional factors*, even though organic findings are present (Group II) This second group is even more important than the first from the standpoint of diagnosis and treatment "

The third group "comprises a group of disorders generally considered wholly within the realm of 'physical disease,' which have to do with the vegetative nervous system, such as *migraine, asthma, and essential hypertension* Psychosomatic medicine is much interested in these disorders because it believes that the psychic factor may be of great importance in their etiology, and, even more importantly, in their management "

II LEVELS OF GROWTH OF THE HUMAN MIND

Every organ and organic system has function The gastro-intestinal tract serves alimentation, heart and blood vessels circulate substances to various parts of the body, kidneys serve elimination, bones form the framework, muscles serve motility, the nervous system coordinates, the totality of these systems, and others, constitute the organism as a whole, so to speak The organism is destined to move about a very complicated environment, to become an integral part of it It starts off

essentially as an organic being and for the first few years its parents act in its behalf in almost all matters, save the purely vegetative. In these early years the mind is budding and it is significant that the mind is made up of components from two general sources, the instincts and the parents. The wholesome child is the one whose training by the parents is in harmony with the environment, on the one hand, and with the instinctual urges, on the other.

Soon the *personality* begins to develop. Presumably the personality (or the psyche, or the mind) is an outgrowth of cerebral activity, it is a function of the brain. In the early months of living the two cannot be differentiated, but, as experiences accrue, the personality grows and grows until it has its own form and functions, which are quite different from those of the brain itself though it never loses its original embedment. The mind (or psyche or personality) may be likened to a tree rooted securely in the earth, yet having its own distinctive qualities fed by the earth, but also by the atmosphere or environment. The tree has its own form and functions, which can be understood not in terms of the soil (brain) alone but particularly in terms of its own qualities and its environment (sunshine, rain, winds, lightning, etc.).

I. THE SOMATIC PHASE

The human mind passes through levels of growth, so to speak. In the beginning the acorn and the soil are as one piece. In the early years of growth the child's mind is made up largely of a knowledge of its physical self and its physical surroundings, reinforced by the instincts which too are largely physical or physically expressed. To designate this level of growth it is said that the mind is essentially *somatic* in its composition. Some people never get well away from this level of adaptation. They meet the environment chiefly in terms of their own organs and organic functions. They become the hypochondriacs, whose socialization is heavily burdened with their organs, their organic functions. When you ask them how they 'are', they take 'they' to mean their heart or lungs or stomach or whatever organ or organic system may be involved. These people do not speak for themselves, they speak for their physiology.

Human beings get extensive training in converging their interests, their emotions upon their organs. It's their first training period, normally it lasts a few years, though in certain families it may be a habit pattern of a decade or more. This is particularly true when the teacher, that is, the mother or father, is preeminently hypochondriacal. *Psychosomatic illness* may and often is fostered by an originally weak and by sustained illnesses. The human being gets extensive a knowledge (good or bad) of his body. Emotions find a substantial pathway to and through the organs of the body and abdominal viscera are predominantly involved.

It is in this early period of growth that the habits, called psychosomatic, gain their best training. It is in this phase of growth, too, when the child is most closely taken care of by its parents. It's a stage of relative ease and contentment, without pressure from the extraparental environment and milieu. Some individuals (hypochondriacs) never essentially abandon the habits of this period. They go through life as children, always looking for the kind parent. They are as parasitic to the physician, for example, as they were to their own parents.

Hypochondriasis that perpetuates itself with perhaps only slight modification into and through adulthood does not respond favorably to therapy. It is an habitual pattern. Another reason why therapy is usually ineffectual lies in the consideration that other, later, more mature patterns are poorly developed. If you take away the hypochondriasis, there isn't anything else strong enough to support the person. The patient knows that and defends himself, perhaps rightfully, against any effort to remove his essential prop.

When, however, hypochondriasis is a phase to which an individual reverts in order to escape from some later type of growth, to which he had more or less successfully adapted himself for an essential period of time, it is often possible to assist him back to the higher level. In these instances the psychosomatic approach will likely produce favorable results, because the patient is not habituated to the somatic type of emotional expression, but has simply fallen back upon it in order to escape a difficult situation, at some other, higher level of growth. Moreover, in these cases as a rule, the diversion of emotions into somatic channels is not diffuse, but is restricted to a single organ. One then speaks of an *organ neurosis*.

Organ neuroses are common in general medical practice. The psychotherapeutic approach to such states has already been described in a case with peptic ulcer as the presenting symptom.

The neurotic component, that is, the emotional conflict, may attach itself to an organically sound or to a pathological organ. Quite apart from the state of health of the organ, the psychotherapy is the same for both. The type of organic therapy to be administered will, of course, depend upon the nature of the organic involvement.

There is a special type of hypochondriasis engrafted upon the hysteroid personality. It is commonly known as *conversion hysteria* and includes one or more of a welter of symptoms—such as anesthesia, paresthesia, paralysis, paresis, loss of function of one of the sense organs (blindness, deafness, etc.), nausea, vomiting, aches in various parts of the body. These, too, may be called organ neuroses. They occupy an unusually favorable position from the point of view of therapy, probably because they occur in individuals who in many respects have often achieved at least fair to middling adaptation to adult levels of behavior. Furthermore, hysterical symptoms are ordinarily episodic.

in appearance and are "used," so to say, only when the adjustment to the higher levels fails

Another form of hypochondriacal expression, one that seems to be losing vogue diagnostically, is *neurasthenia*. It is characterized by easy fatigability, both mental and physical and by a variety of symptoms secondary to fatigue. Patients in this group usually fail to respond favorably to psychotherapy. There is a growing conviction that further research may place the etiology of this disorder in the organic sphere, perhaps under the heading of anomaly of the vegetative nervous system and its adnexae.

The diversion of emotions to organic channels of expression is almost a universal phenomenon among the group of patients with *schizophrenia* or *dementia praecox*. While a great deal is known about the psychopathology of these patients, little can be done therapeutically when the emotions are thoroughly fixed to the organs. Schizophrenia is said to be a regressive mental syndrome, but in many instances it is not regressive for the reason that the individual never did adjust himself well to higher levels. He has little to regress from so to speak. Others who have attained some measure of success may benefit through psychotherapy, especially if they are not too frightened by the ordinary demands of reality.

Since we are presenting here a point of view rather than an organized classificatory scheme it seems unwise to mention other clinical states in which hypochondriasis may appear. We should like to close this section by repeating what was earlier said, namely, that it is natural to the growth of all human beings to pass through a relatively prolonged phase of growth during which the infant's attention is appreciably converged upon the structure and functions of his bodily organs. As we put it earlier, every human being experiences much training in matters psychosomatic. Often the training determines later adaptation to life, often it is the phase of growth to which maladjusted individuals revert. Psychosomatic therapy must include a survey of the early years of growth within the family circle.

2. THE NARCISSISTIC PHASE

The second phase of growth consists largely in the expansion of the child's ego. This process usually starts in the neighborhood of the third year when the child begins to get a large quantity of praise and commendation for good behavior. Verbal and material awards are given for cleanliness, good table manners, politeness, obedience, intellectual display, and so on. Indeed, at no other time in life will this individual get such pure acclaim. He is often made to feel that he is omnipotent and omniscient. The parents, perhaps also grandmothers and aunts, gather in formal silence to hear the new words of wisdom or to witness some remarkable act. Encores are earnestly requested.

Much of the child's energy, formerly devoted to his physique, now moves on easily to the realm of the ego. It is more profitably used there. This is the phase of narcissism or self-love in the ego sense. It is nurtured by the parents for years to come and is one of the strongest ties between parents and child. It is one of the bonds, indeed, the strongest, from which to extricate oneself. It is difficult for normal children to reduce its intensity and it is usually impossible, except through psychotherapy, to do so with those who are anomalous or abnormal in personality development.

We can only mention in passing the many pitfalls that the child may meet. He may be an unwanted child by one or both parents, or they may bring him up as a girl, or he may be early orphaned and brought up by a maiden aunt, or one of the parents may die or leave the family, while the child is young, or one or both parents may be overdevoted to him and cling to him for years. The possibilities are many. We should not forget that the child himself may be unable or unwilling to go on to the next stage of development.

Narcissism, however, in and of itself, is not a psychosomatic problem, but because it is such a close outgrowth of the stage of somatism or body interest, whenever the subject's narcissism is injured (and narcissism is often fragile in the hands of others), the pathway to somatic complaints is short and easy to traverse.

Usually psychosomatic complaints, or should we say physical complaints of mental origin, when seen in the narcissism of hysteria are amenable to psychotherapy. When they are implanted in the schizoid personality, they are more difficult, if not impossible, to remove.

Merely to complete this little survey on narcissism, though basically it is not connected with psychosomatic medicine, it might be mentioned that the compulsive-obsessive form of psychoneurosis is believed to derive most of its unconscious components from the stage of narcissism, although not a few such patients also show some conversion symptoms. Psychotherapy in these cases is, however, largely concerned with the mind and not the body.

3 THE SUIGENERISTIC PHASE

The third stage of personality development, beginning at the end of infancy (fifth year) and terminating at or around puberty, contains elements of the past (somatism and narcissism), to which are now added more or less extensive experiences with members of the same gender. This is the stage of initial socialization and the child spends the years from infancy to puberty, affiliating his interests principally with members of his own gender. That is why the term "sui (one's own) genderism" is used to designate this phase of growth. In the human being the preparation for maturity extends over years. About the first five years are spent in getting used to oneself, physically and

mentally. Of course, this process never ceases. The next six or seven years are spent in getting used to others. To make the latter step as easy as possible the child adapts himself for a long time mainly to members of his own gender. In the meantime he acquires parental substitutes in the form of teachers (scholastic, religious, recreational, etc.).

Usually the associations with one's own gender in this period are nonsexual, but among those who are later to show difficulties in adjustment, the background for homosexuality is laid. Sex first appears during the period of infancy and is directed to the parents, to whom the infant takes all his problems. In the late infancy period he converges his sexual interest upon himself. During the latency period (from infancy to puberty), the child's sexual interests undergo partial sublimation but a large share of it is externalized upon members of the same sex. When the sexual interests are well sublimated, the term *sui-genderism* is used, when they are expressed in nonsexual, but amorous ways, the term *homocrotism* is employed, when the interests are overtly sexual, one speaks of *homogenitalism* or *homosexuality*. Ordinarily the three types of activity appear in the latency period. Subsequent personality growth depends in large part upon the degree of fixation of interests obtaining in this period.

While the majority of individuals relinquish *sui-genderism* in favor of *altrigenderism* (the state of being interested in the other, opposite gender) a certain proportion do not make the change. Some remain overtly homosexual. These people usually have no conflicts about this way of adjustment. Others with overt homosexual experiences try to get away from homosexuality through marriage. These people commonly run into trouble, a fair share of marital incompatibility is based upon this difficulty. Still others can give vent to their homosexuality only under special conditions such as alcoholism and drug addiction. A final group remains the members of which try to keep their homosexuality in deep repression. The repressed homosexuality is so strong, however, that it cannot be kept repressed; it comes out of the unconscious in the guise of symptoms. An outstanding example of the latter is seen in the paranoid form of schizophrenia, the core of which is founded upon delusions and hallucinations of persecution by members of the same gender; often the persecution appears overtly sexual.

The general medical man does not have much to do with those homosexual individuals who express their troubles through psychotic manifestations. He soon turns those problems over to a psychiatrist. But he often sees those whose troubles are fundamentally homoerotic. However, the patient does not go to the physician for correction of his homoeroticism. Too frequently the patient does not see his own problem clearly or if he does he makes an effort to conceal it. He usually presents a physical complaint to the physician. The physical complaint is usually a disguise though neither the patient nor the

doctor may recognize it as such. Ordinary medical means fail to effect a cure, the symptoms persist in spite of good medicine or surgery. An investigation into the living habits of the patient soon reveals psychopathology, namely, that there is considerable incompatibility with the wife, she berating him for his ever-growing passivity to her, he spends most of his time with male companions, he is increasingly irritable to her. He claims that he is very fond of his wife and that it would be pathetic if they had to separate. During further interviews it is established that he married more or less precipitously in order to escape from too close affiliation with men.

Treatment now progresses along both psychical and somatic channels. As the patient gains understanding of his original difficulties, the somatic problem that failed to improve under medicinal or surgical therapy gradually clears up.

4 THE ALTRIGENDERISTIC PHASE

The fourth phase of personality growth, starting in early adolescence, is called the altrigenderistic, it refers to adaptation to the opposite gender. This phase, too, takes years for adequate development. There is little wonder that so many marriages are discordant. Nature must have realized the difficulties attendant upon harmonious marriages, for she extended the period of preparation physiologically up to twelve or thirteen years, to which our legislators add another half dozen years. Yet, overt incompatibility leading to a separation of the parties is relatively uncommon, due in part at least to the generosity of the partners, who usually let the other one fall back upon his or her daily activities. Which is but another way of saying that the partners fall back upon their own narcissism. Usually, however, there is enough altruism to keep the marriage harmonious.

There are very few psychosomatic problems in husbands and wives who get along well together. Those that do appear are mild in character and of short duration.

5 THE PHASE OF ADJUSTMENT—THE IMPERSONAL SIDE OF LIVING

The fifth phase of growth, not comparable chronologically with the other four, starts early in life and is continuous throughout life. It constitutes adjustment to the essentially impersonal side of living, including scholarship, career, recreations, hobbies, and so on. Some individuals, who cannot get along in intimate relationship with people, can meet people very happily by way of their job or career. They personalize their work, so to speak, and they get along well on the basis of personal contacts professionally guided. Others break under the all-work-and-no-play regimen. The latter may ascribe their difficulties to overwork. Overwork, however, is too frequently an effect and not a cause. Psychosomatic problems among the overworked are not un-

common Reduction of hours of toil cannot in itself effect a cure, unless the individual can learn to be a human being among human beings when he is not at work

III THE PERSON IN THE BODY

Personality Defined—When we speak of the character or disposition of a person, we have in mind the organization of his ideas and feelings. The latter are systematized, so to say, they are arranged into a more or less habitual pattern for the given individual, for brevity's sake we call the totality of his ideas and feelings his personality. His personality is the medium through which he establishes relationships between himself and the environment about him, it is the agency through which he expresses his inner wants to the world about him and through which he receives impulses from without. Perhaps this can best be illustrated by reference to the original meaning of the word "personality." It stems from the Latin *persona*, which was "a mask anciently worn by actors, covering the whole head and varying according to the character to be represented." It is broken down still further into *per* (through) and *sonare* (to sound). The personality is the medium through which pass impulses from within and without.

It is not strictly true, however, to conceive the personality as a bridge between the person and his environment, because the only way that the personality can let itself be known is through the organs of the body. Emotions and ideas cannot reach externality save through tissue. Since body tissue is the great conveyor of the impulses of the *persona*, it is understandable that, when we consciously refrain from acting out an urge, the energy of the urge gets held up in the given tissue. The greater the urge that is repressed the more keenly is the body sensation felt, until the subject comes to regard the body sensation as a physical illness. He usually fails to recognize that the body is ill because he unwittingly flooded it with an inordinate quantity of emotional energy.

A young man unduly shy and reserved fell in love with a girl but he was too repressed to let her know it in any way. As his love grew it steadily dammed up within him. He tried to deny to himself that he loved. He began to lose appetite, then to feel sick to the stomach. His feelings were transferred in increasing quantity to the stomach. His feelings gradually left the girl as they were added to the stomach. Examinations by the doctor failed to elicit any organic etiology. A review of the emotional life of the patient soon uncovered the nature of the stomach disorder and psychotherapy released the emotions from their unwholesome attachment. The stomach trouble was cured though it took a much longer time for the young man to follow the doctor's instructions regarding healthy contacts with the environment.

There are several types of personality. The type itself does not

necessarily indicate abnormality. One person may be quiet, reserved, taciturn, yet he may not be at all troubled by his personality. Another one may be lively, talkative, frank and open, but he is well adjusted to himself and to others. A third person may be self-contained, conceited and highly interested in himself, yet he is at ease with himself and does not cause discomfort in others. A fourth is a faddist on health, yet he is not disturbed by his enthusiasms, nor does he try to impose his interests upon others.

Distorted Growths of Personality—As a rule, it is desirable to treat the personality when it becomes extreme in its manifestations, for it is then that the personality is not helping, but is hindering, the individual. It is a valuable working hypothesis to look upon the personality as a distinct part of the human being, as an organ of the body, if you wish, an organ that has heritage, embryology, anatomy (gross and microscopic), physiology and pathology. The personality can have poor hereditary potentialities that may cause it to wear out in the early years of life, in somewhat the same manner that a constitutionally weak kidney, for example, undergoes involution early in life. A weak personality can handicap a career every bit as much as a weak body can.

Or, a constitutionally strong personality may be famished by poor nourishment. It is not a figure of speech to speak of emotional anemia, there is little that is more destructive to the full life of a child than an unloving parent. A child needs affection just as much as it needs nutriment. This was recognized centuries ago by the lexicographers who formed the words *nurture* and *nourish* from the same root word. To nurse, to nourish, to nurture—all have the same origin. Nurture expresses "thoughtful care and moral discipline." It may not be amiss to see in these words the close bond between the mind and the body, to see, in other words, a cogent psychosomatic parallelism.

It is equally injurious to the growing personality to have a plethora of emotions imposed upon it. In *School for Scandal* Sheridan wrote that "your character at present is like a person in a *plethora*, absolutely dying from too much health." Jeremiah Taylor expressed the same idea in these words: "At the same time he is full and empty, bursting with a *plethora*, and consumed with hunger." The overindulgent parent compels the child to gormandize, to take in excess that which is forced upon it. In so doing, the parents distort the natural flow of secretions, which is but another way of saying that when parents do everything for a child they fail to give the child the opportunity to express his own natural self. The child's own inner needs are sacrificed upon the altar of greedy parents.

These are not new ideas by any means. Every doctor, every person knows that these things can and do happen. What we need to know, however, is that these distorted growths of personality are very frequently reflected in the organs of the body in the form of organic

symptoms for which there is no recognizable organic cause. The sufferers go to a doctor with physical complaints. Some of them do not know that the physical complaints are but mere disguises for mental complaints. Others have a vague opinion that there may be a connection. It is traditional, though, to conceal unhappiness and unfortunately many physicians conspire with the concealment. It is as though the physician thinks that unhappiness can be lived out only through the mind, when at a moment's reflection he can recall several of his patients whose physical symptoms disappeared after a good heart-to-heart talk.

Psychotherapy is not, of course, as simple as that, save in a few instances. Psychotherapy has to be better organized, has to be more comprehensive, in the vast majority of patients.

Types of Distorted Personality and Their Treatment—There is a large group of patients for whom the doctor, not a specialist in psychiatry, can do much good. In what is to follow there is a thumb-nail sketch of types of personalities that can be easily identified by the physician, personalities in whom there is very often a shifting of emotional troubles to physical areas (heart, lungs, stomach and so forth). Treatment of the personality, when undertaken early in the illness, often leads to good mental and physical health.

I SCHIZOID PERSONALITY

Some children are born quiet and reserved; others acquire those traits, while still others have them thrust upon them. In each instance, however, the traits are modifiable to a greater or lesser extent. The schizoid individual is an *introvert*, a quiet, seclusive, taciturn person who is ill at ease with people. He gets along far better with the inanimate world though he is able to meet others by way of intellectual rapport. He finds it very difficult to emotionalize his interests unless he emotes upon the impersonal. He may be communicative as regards his intellectual pursuits but he seldom reveals anything about himself as a human being with deeply living feelings. Usually he leads a rich phantasy life which, however, he keeps to himself and it is into his phantasies that he pours his feelings. His feelings remain within him; he is introverted. The schizoid individual is prone to divert his emotions from his phantasies into one or more organs or organic systems; that is, he is inclined to be also hypochondriacal. His hypochondriasis is often regarded by him as the real reason why he does not spread his interests among people, why he does not participate in recreations. If he has a hobby it is of the lonely type, or at least, he makes it so.

The schizoid person seldom goes to a doctor for his schizoidism. Rather, he presents the organic aspect of his trouble for which, of course, no organic cause is detectable. Medicines may be taken for months or years yet the symptomatology remains unchanged. After

surgical operations—let us say, after an appendectomy—the course of the complaints is the same as it was before the operation. While the stomach is a favorite organ in which to lodge the emotions, the eyes and nose run a close second. The best talents of the ophthalmologist and rhinologist fail to remove symptoms for the simple reason that neither lens nor resection of a septum touch the emotions. It is only too well known that “sinus” (of hypochondriacal origin) survives all medical and surgical skills, indeed, the latter lend plausibility to and perpetuation of the symptoms.

When shut-inness (schizoidism) grows progressively more intense, it is not unlikely that it may lead to schizophrenia (dementia praecox). The need for psychotherapy during the stage of schizoidism is obvious.

Treatment of the Schizoid Personality—*A slow and steady habituation of the emotions to natural environmental interests* is the core of treatment. The subject should align his interests with a group or two, perhaps, it might be well to have him join some informal educational group, the kind that serve collations with their scholarship, so that he might be gently introduced to the human side of life. It must be remembered that the schizoid person is afraid of human relationships, often as afraid as the normal person is of some real impending catastrophe. He really is. He should not be hurried. If you hurry him you may have to treat his “sinus” for a much longer period than you would treat his personality.

He should affiliate his recreations with others. If stamp collecting is his hobby he should be encouraged to socialize the hobby, to make it a means of meeting people for more than philatelic reasons. It is not unlikely that he may come to feel at ease with some eligible young lady via stamps. And the interest in her may bear that imprint for a long time. Don't hurry him. Falling in love (without stamps) is one of his most difficult tasks. If it is forced he may recoil and fall back upon his “sinus.”

It is a grave mistake, one that is repeated daily, to advise a schizoid individual to “go with a girl.” The advice is not only gratuitous, it is injurious, for the result is usually a shocking failure. This person, perhaps more than others, needs months of training and experience in ordinary social amenities before he is ready for intimacies.

He must be gradually weaned from home and parents, particularly from mother. Don't be discouraged if progress is slow. Remember that nature allows about twenty years to cover the transition from mother to another girl and another home. You ought to allow at least a year. If you don't, you'll be treating the “sinus,” if not something more disabling, for years to come. Patience is the keynote. The instincts will protest against delay, they don't know the pitfalls of premature hurry. Instincts destroy what they would best preserve.

Direct psychotherapy must be carried out at the same time. Encourage the patient to tell you about himself, about everything that has gone into his life. It is notorious how poorly learned these people are in matters of ordinary life. They have shut their eyes to human nature and have constructed their own meaning of what they observe about them. Usually they grow up in a detached sort of way. The "knowledge" they have of human relations is a product of their imagination. The physician can do much to clarify the physiology of the mind, of the body, of the herd, of the society in which he lives.

This all-too-brief delineation of the schizoid personality is intended to show the relationship between the person and his organic symptoms, and to show the way to a psychotherapeutic approach. It indicates a psychotherapeutic approach that can be used by any physician in the treatment of early psychosomatic states. Indeed, psychotherapy is most efficaciously applied when the problems are in the personality only, that is, before the problems appear in the form of organic symptoms.

2. CYCLOID PERSONALITY

While it is valuable to divide personalities into categories, it should be realized that nature is not as strict as man is. Generally an individual is preponderantly, but not exclusively, of one type or another. Hence, in the examination and treatment of a given patient, we should be thoroughly familiar with the remaining categories.

The cycloid personality in one of his phases is characterized by *extra-ersion*, by a tendency to combine his interests inordinately in other people and other things. *He is the kind of person who subordinates his inner life to environmental needs.* It is said that he "flees into reality." He works long hours, has many irons in the fire, is full of optimism and enthusiasm, and is ever ready to talk about his projects. He usually has a great desire to get to the top, even his play carries the stamp of work and ambition. He often shows what is called a holiday or a "Sunday" neurosis by which is meant that, when he finds himself idle and relaxed, he promptly prepares to be busy with something.

There is a meaning behind his incessant activity, a meaning that often spells trouble. Why does this fellow have an insatiable need to absorb so much of the environment within himself? Why does he not relax and from time to time look to his inner self? Why is he so busy covering himself up with a thick career blanket? His *persona* is clearly a mask and much to his distress he knows it whenever he takes a moment off for reflection.

The trouble with this person lies in the consideration that he is constantly covering up his inner self with a welter of impersonal activities. His inner self is not allowed free and easy access to the environment. A short peep and then it is pushed back by work a-day.

problems This denial of adequate outlet for the qualities of human nature may be sustained for a long time, but it usually leads to great unhappiness, if not to a formal mental disorder (viz, manic-depressive psychosis)

Those who are close to such a person usually describe him as both a very capable man in business and, at the same time, a boy, he is mature and immature, mature in his career, immature in his emotions When his friends compel him to relinquish work for play, he is abashed and almost helpless, unless the play is childish, under which circumstances, he may be the life of the party He is the type of person who never had a childhood or adolescence, save in a perfunctory sort of way A whole block of his life has been taken out, or, better, was never lived through He went from early childhood to maturity Nature avoids, or tries to avoid, a mental vacuum as well as a physical one That is the reason why these people are usually unhappy That is the reason why, when they develop a frank maniacal attack, they live out extravagantly all and more that they had missed in former years

The cycloid personality in his other phase, and usually there is another one, gradually gives up his great output of energy, his boundless enthusiasm, his friendliness to their opposites, namely, to inertia, pessimism and seclusion He counts his past accomplishments as failures because they were performed automatically, he tells you that they were simply intellectual deeds, that only his head, not his heart was in them He emphasizes the futility of his past and he is right, for was he not an automaton, who substituted a career for wholesome living? He is dogged by his alleged inadequacies In this depressive stage his feelings of inferiority stand out in bold relief and he realizes how little he is a part of the human world around him

In the phase of depression the emotions, which formerly were externalized, are now internalized, they overwhelm him, spread throughout his body, giving rise to all manner of physical complaints It is as though the emotions stopped all his physiology, save that necessary for the minimal maintenance of life In no other clinical state is the psychosomatic relationship more widespread, more hampering The emotions blanket the body as sand does a fire

Treatment of the Cycloid Personality—There are many relatively mild states of cycloidism, many persons who shift from phases of happiness to those of depression When the stages are severe, leading to the diagnosis of manic-depressive psychosis, the illness should be treated by a psychiatrist But the milder states of cycloidism are usually first seen by other physicians and again, as in schizoidism, the patient presents the organic manifestations of his troubles And, again, no organic etiology is detectable Seldom does the subject ever appear

before the doctor while in the up-swing stage, because then he is confident and sure of himself and physically he feels perfectly fit.

Treatment of the individual in the depressive state is both somatic and psychic, with greater emphasis on the latter. All available measures for good physical hygiene should be instituted in order to combat the deleterious influences that the emotions are playing upon the body. The physical measures necessary to maintain some semblance of health are well known to the physician.

Psychotherapy should be promptly instituted. In the beginning *persuasion* and *assurance* are highly desirable, for the patient needs to be considerably supported mentally. He is like a lame person—hurt by walking, afraid to take the next step. He should not be encouraged to take complete rest first, because rest only gives him more time to bemoan his lot in life, and, second, because some constructive activity, however meager, buttresses his morale. Keep him going with activity commensurate with his capacities.

The patient needs someone to lean on, someone to whom he can relate his troubles, someone to whom he can transfer his feelings. If the depression is mild, the assurance type of therapy does not have to be kept up long. The physician might begin to use the more fundamental treatment, namely that which is designed to remove the cause of the illness. Assurance is merely treatment of the symptoms. Deep psychotherapy aims at the cause.

The purpose of *deep psychotherapy*, as practiced by the nonspecialist, is to make an extensive inventory of the patient's life, past and present. That is done directly through the patient, who gains emotional outlet and insight into himself while reviewing his life. By this means emotions are drawn away from the body, as they are being drawn away, they should be redirected upon natural environmental interests. The best technic on the part of the physician is to be a good and interested listener and a judicious adviser. In psychotherapy the patient does most of the work. Let him assume and maintain leadership in the interviews. The physician should be like the pilot who turns over the controls to the trainee. To do this properly takes much training and experience, for in all other treatment procedures, the physician is conditioned to taking over full control and the patient is accustomed to follow. *The traditional patient-physician relationship is reversed in psychotherapy.* This arrangement does not by any means negate the physician's influence; on the contrary, it enhances it. He becomes the trainer rather than the pilot. When he tries too much to be both, his student does not learn. Let the student observe and interpret the several dials on the instrument panel, correct him when he is in error.

Gradually the patient will see what he previously had not seen; he had not seen it because he did not want to and he did not know how.

to see himself as others saw him. He will steadily find out how blindly he had been going through life, how blind he was to his faulty ways, how, without knowing it, he was driving furiously ahead without regard to warning signals. He will soon know how dangerously he negotiated a certain curve, merrily on two wheels, without taking his foot off the accelerator. He will soon know that he should not have driven steadily for eight hours, but that he should have stopped for refreshments and relaxation after each few hours. He will understand that he should not have bragged about the great speed he made over a long course. It was that kind of driving that eventually wore out the driver and the car prematurely.

Then, when he has seen himself, he is prepared to slow down to reasonable speed. The slowing down is not easily done, but with time and experience he will like it far better than he liked the dangerous way. He will not take rest and recreational periods easily at first, because he was gauged to speed and ambition, but when he learns that the pleasures of relaxation with people are at least equal to the pleasures of stiff, professional competition, he will wish to experience both.

He will believe you when you say, "Don't build a palace on quicksand."

3 HYSTEROID PERSONALITY

Some people are always in groups though not a part of them. They are lonely mixers, unless they can cause the interests of the group to be essentially converged upon them. They contact reality richly so long as reality focuses its attention upon them. They are perennial children always seeking the admiration of the parents. To them the people of the world are divided into two groups, mothers and fathers. They are greatly pleased with adulation, though they may not have earned it through any meritorious accomplishment. They are as proud over a comment made on the neatness of their appearance as they were when the family admired their first party dress. That is natural, you will say, but it is the *incessant bid for attention* that stamps the reaction as anomalous.

The hysteroid person shows very facile emotions. Laughter, tears, anger appear with ease and are usually occasioned by the attitude of others toward the subject. It is easy for him (though hysteroidism is preponderant among females) to sympathize with others, often to the extent of acting genuinely like another. He is oversuggestible. Indeed, a major fault with him is that he can far more readily be another than he can be himself. He is a play-actor, so to say, and in this respect he can often simulate, without knowing it, the physical ailments of another. This is especially true when his selfishness is punctured. Like a child who has learned the value of sickness, real or feigned, he can and does resort to it, when other means of gaining attention fail.
